scopic evaluations When conductive losses were demonstrated masked bone conduction was utilized to obtain a reasonably accurate pattern of the sensorineural reserve

Available English articles and abstracts relating to the syndrome of hereditary hearing loss with nephropathy have been reviewed and an analysis of the hearing pattern and otologic findings in 54 affected and unaffected family members is presented

PART I

Review of the Syndrome

The concept of nephritis occurring on a hereditary basis apparently was not introduced into the medical literature until late in the nineteenth century The earliest report that could be found by the author was by Samelsohn in 1874 (12). This German author mentioned the similar character of a familial form of a renal disease to glomerulonephritis The next year an English author Dickinson, referred to three generations of a family in which 11 out of 17 members had albuminuria and several died prematurely of Bright's disease (13) A few scattered reports making reference to a hereditary pattern in renal disease appeared in the next 25 years. Kidd in 1882 (14) Benson in 1893 (15), and Pel in 1899 (16) described a hereditary background of nephritis extending over two more generations. Attlee (17) mentioned renal disease affecting several family members simultaneously but the hereditary nature of thi familial pattern was not elucidated Aitken (18) in 1909 documented the finding of albuminuria and hematuria in several generations, and Eason and Smith in 19 4 (19), reviewed the pattern of hereditary nephritis with the addition of another family Two cases of hereditary nephritis were reported in Germany in 1906 (20).

A most remarkable study developed from a family urvey first carried out by Guthrie in 190 (1) The family was kept under surveillance for a period of 25 years at Guy's Hospital in London, and reports were made by Kendall & Hertz in 191 (22), and by Hurst in 1915 and 19 3 (23 4) The author believes that Hertz & Hurst were the same man because the first and middle names are the same Cecil Alport presented the quarter century report on the family in 1927 (25) He was the first author to comment on the hearing loss as a distinctive feature of the syndrome and Williamson in 1961 (26) suggested that his name be applied to the combination of hereditary nephritis with deafness. Williamson stated.

> Reports of this syndrome have appeared under different descriptive titles which are often rather cumbersome and, since the aetiology is still unknown, may well be inaccurate. It seems, therefore, that a case can be made for the use of an eponymous title, at least for the time being. If this is accepted, then Alport's name is the obvious choice since it was he who first described the main features of the syndrome. I suggest, therefore, that the syndrome should in future be referred to as Alport's syndrome

Alport reviewed four generations of the family and reported the case studies of 29 members. Seven males and 7 females showed evidence of nephritis and 5 of the males had died before they were 20 years of age The oldest male survivor with hearing loss and nephropathy was only 13 years old. Average life span occurred in all females except one. Seven females and 4 males were noted to have perceptive deafness. He labeled the disorder hereditary familial, congenital, hemorrhagic nephritis. Alport also made the observation that the disorder was more severe in the male yet transmitted by the female and that nerve deafness may exist in individuals who are otherwise healthy The family he reported on apparently was considered to be a medical oddity and of little general interest, because only one mention was made of hereditary nephritis over the next 25 years. This was a report by Rinloff (27) in the United States in 1939 and it apparently represents the first sugges-

scopic evaluations. When conductive losses were demonstrated masked bone conduction was utilized to obtain a reasonably accurate pattern of the sensorineural reserve

Available English articles and abstracts relating to the syndrome of hereditary hearing loss with nephropathy have been reviewed and an analysis of the hearing pattern and otologic findings in 54 affected and unaffected family members is presented.

auditory disease related to such causes as drugs and infection.

Sohar was the first investigator to recognize the fact that certain ophthalmological defects were present in patients with hereditary deafness and nephropathy. He reported first from Israel in 1954 (35), and later in the United States (36) on a Jewish family. Four sons of the propositus were noted to have severe nephropathy with two having associated spherophakia and the two others posterior cataracts, apparently congenital. After Sohar's report other authors recorded eye abnormalities related to the lens, particularly lenticonus (36, 37). An increased incidence of myopia (1), cases of nystagmus (38), fundus changes (39, 40), dyschromatopsia (39) and strabismus (40) have been reported but some of these may represent complications of a chronic renal and metabolic state. The association of ocular abnormalities is generally considered part of the syndrome now. Further discussion of the eye changes is presented later but the author encountered very few eye abnormalities in the family members examined by him.

Perhaps malformations of the urinary tract should also be included as part of the syndrome since structural abnormalities have been reported by a number of authors who summarized cases or carried out family surveys (2, 43, 44, 52, 91, 93, 94). The association of genitourinary tract abnormalities in general, however, with otologic disorders is well documented in the medical literature (107, 108) and there may well be nothing specific about the association of hereditary nephritis with malformations of the genitourinary tract.

Genetics

A very detailed genetic evaluation of the syndrome and proposals to explain the mode of inheritance was recorded by Cohen and his fellow workers in 1961 (49). They tabulated four suggested inheritance patterns which included the following: 1) Partial sex-linked dominant, 2) autosomal dominant, 3) intrauterine infection or transplacental nephrotoxin and 4) preferential segregation and chromosomal association. In his report of three families from Greece, Tiliakos stated in 1964 that during cell reduction a crossing-over may have intervened and the X-chromosome crossed to Y-chromosome and vice-versa. Thus, a male patient may transmit the abnormal gene to the male child to which he transmits only Y-chromosomes. Tiliakos also performed karyotype examinations of female and male family members and found no abnormalities. The number of individuals examined is not known (40). Arnott suggested in 1966 that the defect for renal and ocular disease is inherited as a dominant but that manifestation of the gene is weakened by the presence of a sex-linked modifying gene of high incidence in the general population (42). Peters mentioned the possibility of there being one abnormal gene located in the X-chromosome (86).

Genetic delineation of the syndrome cannot be easily explained because both males and females manifest all components of the disease yet it is exceedingly more aggressive in some male siblings than others. Furthermore, the disease may be seemingly absent at birth yet become manifest in the second decade with rapid demise in the male and low-grade subclinical nephropathy and sensorineural hearing loss in the female. In addition, females may carry the trait for renal disease yet show no abnormalities on urinalysis. Pedigree documentations have been very extensive in some instances and investigators wishing to study the genetic patterns of this disease or of sex linked disorders in general should examine in detail the reports of Perkoff, Stevens, Shaw & Glover, Alport, Dubach & Minder, Tiliakos,

tion of the syndrome in America Rinkoff summarized the fatal cases of three brothers and reviewed the literature on hereditary nephritis up until that time He made no mention of hearing loss and postulated that the disease developed from a decreased renal resistance to inflammation and from hypersensitivity phenomena.

Perkoff and his fellow investigators spent over 10 years studying two Mormon families and published several reports of their clinical genetic and pathological findings (7 28 29 30 31 32 33) They documented the significance of white blood cells and bacteria in the urine of family members as well as the hematuria related to glomerular disease Their initial study was actually entitled Hereditary Interstitial Pyelonephritis" and it was apparently in the light of prolonged follow up that they realized the hereditary pyelonephritis in their patients was a form of the disorder described by Alport and reviewed by Rinkoff They concluded that the associated infection was somehow related to a local renal metabolic abnormality of unidentified nature These studies first reported in 1951 probably represent the initial modern studies of the syndrome

Following the revitalization of interest in hereditary deafness and nephropathy by Perkoff and his group numerous studies were initiated throughout the world and reports began to appear from Canada, France Germany Italy Israel Greece Switzerland and Japan (34–106) A list has been prepared showing authors reporting on the syndrome in the past one hundred years (Table I) Aside from the papers relating to genetics, ophthalmologic changes pathology and metabolism which are documented later these are reviews of families with the syndrome and case reports. The disease pattern is extremely variable and may include clinical pictures resembling various types of renal and auditory diseases The author has attempted to prepare a list of reports dealing basically with familial hereditary deafness and nephropathy but not covering renal and

auditory disease related to such causes as drugs and infection.

Sohar was the first investigator to recognize the fact that certain ophthalmological defects were present in patients with hereditary deafness and nephropathy. He reported first from Israel in 1954 (35), and later in the United States (36) on a Jewish family. Four sons of the propositus were noted to have severe nephropathy with two having associated spherophakia and the two others posterior cataracts, apparently congenital. After Sohar's report other authors recorded eye abnormalities related to the lens, particularly lenticonus (36, 37). An increased incidence of myopia (1), cases of nystagmus (38), fundus changes (39, 40), dyschromatopsia (39), and strabismus (40) have been reported but some of these may represent complications of a chronic renal and metabolic state. The association of ocular abnormalities is generally considered part of the syndrome now. Further discussion of the eye changes is presented later, but the author encountered very few eye abnormalities in the family members examined by him.

Perhaps malformations of the urinary tract should also be included as part of the syndrome since structural abnormalities have been reported by a number of authors who summarized cases or carried out family surveys (2, 43, 44, 52, 91, 93, 94). The association of genitourinary tract abnormalities in general, however, with otologic disorders is well documented in the medical literature (107, 108) and there may well be nothing specific about the association of hereditary nephritis with malformations of the genitourinary tract.

Genetics

A very detailed genetic evaluation of the syndrome and proposals to explain the mode of inheritance was recorded by Cohen and his fellow workers in 1961 (49). They tabulated four suggested inheritance patterns which included the following: 1) Partial sex-linked dominant, 2) autosomal dominant, 3) intrauterine infection or transplacental nephrotoxin and 4) preferential segregation and chromosomal association. In his report of three families from Greece, Tillakos stated in 1964 that during cell reduction a crossing-over may have intervened and the X-chromosome crossed to Y-chromosome and vice-versa. Thus, a male patient may transmit the abnormal gene to the male child to which he transmits only Y-chromosomes. Tillakos also performed karyotype examinations of female and male family members and found no abnormalities. The number of individuals examined is not known (40). Arnott suggested in 1966 that the defect for renal and ocular disease is inherited as a dominant but that manifestation of the gene is weakened by the presence of a sex-linked modifying gene of high incidence in the general population (42). Peters mentioned the possibility of there being one abnormal gene located in the X-chromosome (86).

Genetic delineation of the syndrome cannot be easily explained because both males and females manifest all components of the disease yet it is exceedingly more aggressive in some male siblings than others. Furthermore, the disease may be seemingly absent at birth yet become manifest in the second decade with rapid demise in the male and low-grade subclinical nephropathy and sensorineural hearing loss in the female. In addition, females may carry the trait for renal disease yet show no abnormalities on urinalysis. Pedigree documentations have been very extensive in some instances and investigators wishing to study the genetic patterns of this disease or of sex-linked disorders in general should examine in detail the reports of Perkoff, Stevens, Shaw & Glover, Alport, Dubach & Minder, Tillakos

Graham Robin, and Cohen The family studies of these authors cover many *generations* and in the case of Alport extend over periods as long as twenty five years A review of records from Switzerland permitted Dubach & Minder (8 57 74) to chart the pedigree of eight generations dating back to 1730 Other detailed geneologies are under continual surveillance such as those of Perkoff (32) and Sturz & Burke (93) and with the use of computer recording and mass screening devices more complete information relating to details of chromosome patterns, metabolism hearing loss and minor anomalies can be assembled

In 1961 Shaw & Glover (99) suggested that the trait for renal dysfunction and hearing loss is inherited as an autosomal dominant with nonrandom segregation and preferential association of the autosome carrying the gene with the X-chromosome Using a study of five families Cohen and his co-workers further supported this mode of inheritance and documented how this mechanism would explain the observed disorders They studied 339 members of four generations and concluded that the syndrome is not inherited as a partially sex linked dominant or as an autosomal dominant trait giving classical mendelian segregation ratios They stated that the trait is definitely inherited as an autosomal dominant and that the chromosome in which the defective gene resides may be preferentially selected in association with the X-chromosome. The explanation is best understood by quoting Cohen's report from the American Journal of Human Genetics. "During oogenesis in affected females, the autosome bearing the mutant gene may generally pass into the primary oocyte rather than into the polar body The defective gene would, more often than not, be incorporated in the functional ovum which would lead to an exess of affected offspring of both sexes. During spermatogenesis in affected males, the association of the X-chromosome and the trait bearing autosome would cause the two chromosomes to move together preferentially but at random to either pole leading to an excess of affected daughters and normal sons" (49)

Authors reporting on the syndrome should probably test this hypothesis using their genetic data or perhaps test one of the alternatives to see which best explains the observed number of disorders. Certainly even more valuable statistics might be collected if prospective studies aimed at predicting the affected individuals could be set up

Renal Pathology

The specific kidney disorder has been variously catalogued during the past century in a number of ways Autopsy and renal biopsy information have documented patterns consistent with glomerulonephritis pyelonephritis and interstitial nephritis (33 36 70 101 102) In renal biopsies of a case followed for ten years by Van Buchem the primary disorder has been considered to be in the distal tubules with progressive involvement of other renal structures as the patient grows older (101) Most cases of the classic syndrome have demonstrated certain findings of glomerulonephritis on biopsy or post-mortem examinations In addition a recording of renal foam cells is often made and Perkoff noted these frequently in specimens obtained from his family members (7) The lipidcontaining foam cells were noted by other observers also (6, 50 52 60), and were thought at one time to be pathognomonic of the hereditary syndrome and specific enough to permit pathologists to confirm the diagnosis with renal biopsy However Whalen who examined some of the patients reported in Part II by the author reviewed 105 consecutive cases of pyelonephritis and

105 consecutive cases of glomerulonephritis and demonstrated that the foam cells were present in disease states having no basis in heredity and, therefore, were not pathognomonic (102). Whalen also noted that the foam cells probably contained fat, mucopolysaccharides, phospholipids, cholesterol and phosphatides. A pathological picture resembling pyelonephritis can definitely be found in some patients with the syndrome (28, 60, 70, 87) but this may represent a body stress effect with lowered resistance in a target organ as suggested by other authors (1). Generally speaking, the pathologic diagnosis in young individuals has been glomerulonephritis while that in older patients has usually been pyelonephritis.

Various renal symptoms and signs are seen in the disease with hematuria being the initial and principal finding. It has been documented in a ten day old infant (73) and may occur insidiously and subclinically throughout life. At various stages of the disease proteinuria, pyuria, cylindruria and amino-aciduria may occur (67, 74, 94, 95, 96, 97, 106). Urine cultures are usually negative. The documentation of renal dysfunction can be quite difficult and some sort of standard is needed to classify the particular patient as being involved or free of the syndrome. One survey used only fresh centrifuged urine with three red cells and/or five white cells per HPF or an abnormal Addis count as evidence of renal dysfunction. Isolated proteinuria was not considered evidence of disease (1). Perhaps strict criteria such as this would permit more accurate identification of affected relatives of diagnosed patients.

In 1966, a classic paper detailing the pathology in nine autopsy and seven renal biopsy cases was presented by Krickstein, Gloor & Balogh (68). In this scholarly work the authors described in great detail the pathological picture of hereditary nephritis and indicated that there were two major facets to the disease. First, hereditary nephritis usually shows a combination of certain features of glomerulonephritis, pyelonephritis and interstitial nephritis but also lacks certain characteristics of each of these forms of nephritis. A "mixed" type of nephritis thus seems to be the distinctive feature of the hereditary syndrome somewhat analogous to the mixed tumor of the parotid. Secondly, according to Krickstein, the occurrence of foam cells in a practically specific distribution in the lower renal cortex helps to establish the unique histological appearance. Although the foam cells are seen in other types of nephritis, no other type shows them with the same consistency, quantity and distribution as does hereditary nephritis. They state that the foam cells are derived from tubular epithelial cells which have undergone degenerative changes.

The pathogenesis of the renal disorder remains in doubt, but several theories have been proposed by Krickstein and his associates. There may be a family susceptibility to beta hemolytic streptococci, or a structural embryopathy occurring at the time of formation of the renal and auditory systems may exist. An inherited defect of fat metabolism may exist, but there is no evidence of this in other organs. They favor the idea that a genetically controlled defect in an enzyme system common to the renal, auditory and ocular tissues is present. This defect renders these structures susceptible to harmful affects of various types and may lead to the accumulation of a toxic metabolic product with slowly progressive damage to the organ systems involved. This common susceptibility is seen in normal individuals from the ototoxic and nephrotoxic affects of certain drugs like kanamycin. This inborn metabolic error of metabolism would explain the normal renal biopsy reports seen early in the disease with progression to nephritis later (101). The renal biopsy studies of Krickstein indicate, however, that foam cells may be picked up early in the disease before other changes have become pronounced and thus alert the pathologist and the clinician to the likelihood of hereditary nephritis.

Schriver in 1961 (95, 97) and Schriver, Efron and Schaler in 1964 (96) reported

Graham, Robin, and Cohen The family studies of these authors cover many generations and in the case of Alport extend over periods as long as twenty five years A review of records from Switzerland permitted Dubach & Minder (8 57 74) to chart the pedigree of eight generations dating back to 1730 Other detailed geneologies are under continual surveillance such as those of Perkoff (32) and Sturz & Burke (93) and with the use of computer recording and mass screening devices more complete information relating to details of chromosome patterns, metabolism hearing loss and minor anomalies can be assembled.

In 1961 Shaw & Glover (99) suggested that the trait for renal dysfunction and hearing loss is inherited as an autosomal dominant with nonrandom segregation and preferential association of the autosome carrying the gene with the X-chromosome Using a study of five families Cohen and his co-workers further supported this mode of inheritance and documented how this mechanism would explain the observed disorders They studied 339 members of four generations and concluded that the syndrome is not inherited as a partially sex-linked dominant or as an autosomal dominant trait giving classical mendelian segregation ratios They stated that the trait is definitely inherited as an autosomal dominant and that the chromosome in which the defective gene resides may be preferentially selected in association with the X-chromosome The explanation is best understood by quoting Cohen s report from the American Journal of Human Genetics. "During oogenesis in affected females, the autosome bearing the mutant gene may generally pass into the primary oocyte rather than into the polar body The defective gene would, more often than not, be incorporated in the functional ovum which would lead to an exess of affected offspring of both sexes During spermatogenesis in affected males the association of the X-chromosome and the trait bearing autosome would cause the two chromosomes to move together preferentially but at random to either pole leading to an excess of affected daughters and normal sons" (49)

Authors reporting on the syndrome should probably test this hypothesis using their genetic data or perhaps test one of the alternatives to see which best explains the observed number of disorders. Certainly even more valuable statistics might be collected if prospective studies aimed at predicting the affected individuals could be set up

Renal Pathology

The pathogenesis of the renal disorder remains in doubt, but several theories have been proposed by Krickstein and his associates There may be a family susceptibility to beta-hemolytic streptococci, or a structural embryopathy occurring at the time of formation of the renal and auditory systems may exist. An inherited defect of fat metabolism may exist, but there is no evidence of this in other organs. They favor the idea that a genetically controlled defect in an enzyme system common to the renal, auditory and ocular tissues is present. This defect renders these structures susceptible to harmful affects of various types and may lead to the accumulation of a toxic metabolic product with slowly progressive damage to the organ systems involved. This common susceptibility is seen in normal individuals from the ototoxic and nephrotoxic affects of certain drugs like kanamycin This inborn metabolic error of metabolism would explain the normal renal biopsy reports seen early in the disease with progression to nephritis later (101) The renal biopsy studies of Krickstein indicate, however that foam cells may be picked up early in the disease before other changes have become pronounced and thus alert the pathologist and the clinician to the likelihood of hereditary nephritis

Schriver in 1961 (95 97), and Schriver Elron, and Schafer in 1964 (96), reported

that hereditary nephritis is associated with hyperprolinemia and hyperaminoaciduria A common transport system for renal tubular re absorption is shared by the amino acids proline hydroxyproline and glycine according to these investigators This metabolic defect has been studied by other investigators particularly Minder & Dubach (8 57 66 67 74 82, 106) They observed hyperprolinemia in six of 21 siblings who were related to a known family with nephropathy Hyperaminoaciduria was found in eight of the 21 siblings Methyl histidine excretion in the urine of family mem bers was also noted by these authors They interpreted these findings as a mute" factor however probably indicating inheritance from one parent that occurred coincidentally in con junction with the abnormal gene for ne phropathy from the other parent. One author has also reported amino-acidurias involving alanine glutamic acid histidine and threonine in the syndrome but no other confirmation of this could be located by the author (82)

Chappel stated that there were abnormalities in the alpha 2 fraction of the serum globulin but this was refuted in reports by others (1 51) No general metabolic error other than a possible enzyme system common to the kidney ear and eye has been identified Johnson points out the curious fact that the structures involved in this syndrome are those in which substance are concentrated against a gradient (kidney) or in which the contained fluids are not readily accessible to the systemic circula tion (cochlear and lens) (2) Perhaps prospective studies in the future will be designed to permit tissue culture or analysis of kidney lens or cochlear fluids Such studies on tissue from affected patients might identify certain defective enzyme systems or abnormal toxin accumulations.

Temporal Bone Pathology

A complete histological study of the inner ear changes in hereditary hearing loss and ne phropathy was not reported until late in 1968 (5) Winter and his co-workers obtained the temporal bones on a 22 year-old white male who died with the syndrome and who gave a history of hearing loss extending back to age 12 and of albuminuria documented at age 5 years The patient was approaching a terminal state and had severe loss of hearing for middle frequencies primarily Bilateral anterior len ticonus was found Winter was struck by the minimal changes on the temporal bone sec tions The tectorial membrane organ of Corti and Reissner s membrane all were normal There was vesicle formation in the spiral liga ment of each basal turn and some degenera tion of the spiral nerves supplying the basal turns with approximately 50% reduction in basal turn spiral ganglion cells Similar vesicle formation was noted under each utricular macule Both temporal bones were essentially identical as were the audiograms recorded nine months prior to death

These findings are probably the classic tem poral bone changes of the syndrome because a similar pathologic picture was recorded in the post-mortem report of two of three brothers dying of the syndrome by Minder & Dubach in 1965 (74) Professor Nager of Zurich who performed the temporal bone examination on the two cases also recorded an atrophy of the spiral ganglion cells in the basal turns More complete histological or audiometric informa tion is not available in this report.

Perkoff submitted the temporal bones in one of his cases to Victor Goodhill for sec tioning but Goodhill recorded that cellular detail was poor and adequate evaluation of the organ of Corti was not possible No distinct histological abnormalities were noted Hy perostosis at the tip of the cochlea was men

tioned but the patient was a 62-year-old female (7) None of these reports make mention of any inflammatory disease of the middle ear or mastoid.

Obviously only a sparce auditory-pathological correlation has been made in the syndrome and a distinct effort is needed on the part of otologists to obtain properly prepared temporal bones for study The author is now following a number of patients with the disease and has contacts with one large family that will hopefully cooperate for post-mortem study The three kindred reported in Part II of this paper are located in another state than that where the author currently practices and are not readily accessible. Temporal bone laboratories are widely available now and internists and pathologists should be apprised of this fact and encouraged to cooperate.

Audiometric Abnormalities

An otolaryngologist, Mr I Gay French, examined two of the cases from Alport's family in 1916 Progressive hearing change was noted in one case and both were diagnosed as having nerve deafness. Alport also noted that the hearing loss was present in some patients who did not manifest nephritis (25) Throughout the family reports in the last forty years sensorineural hearing loss has been the hallmark of the hearing component. In the families studied early by Perkoff, 14 out of 59 members were reported as having abnormal audiograms (28). A separate report on these patients by Stevens and Perkoff indicates that the hearing deficit was found only in males and varied from high tone loss to a moderately severe deafness. They stated that two small groups showed a high tone loss or a dip at 4096 respectively (33) In a later report on these patients 86 audiographic studies were performed. The audiograms of 20 males and one female showed high tone deafness. Two males and four females had abnormalities in the high tone range of doubtful significance The conditions under which these tests were made is not known nor do they record their criteria for determining deafness. Out of a total of 168 family members examined by Perkoff, 22 males and 44 females had no indication of renal or ear disease. Twenty-three patients (two males) had normal hearing with definite renal disease and only six males had hearing loss with normal kidney function. It was his observation that the nerve deafness usually manifested itself in males as the renal disease became severer (7)

Most family members will show close to normal findings on audiometry and controlled conditions are necessary to evaluate early carriers or affected patients with the disease Further discussion of controlled audiometry is given in Part II of this paper

A large audiometric survey done under field conditions showed almost half of the patients with renal disease will have normal hearing (1) These authors used as a criteria for deaf" either clinical impairment of hearing or documented audiometric deficit of 0 decibels or greater at 4 000 cycles per second or more. The controlled audiometry from this survey with compensation for conductive loss is reported in Part II. Reyersbach & Butler documented 12 cases with nerve deafness in 1954 (91) Sturz & Burke recorded a loss of hearing of 30 to 50 decibels in the range of 500 to 4 000 cps in a 7 year-old boy Several relatives of this case also had documented nerve deafness according to these authors (100)

The detailed survey carried out by Perrin in 1964 (38), showed that bilateral perceptive deafness was present in those affected members with hearing loss. Minder and Dubach first reported that 12 out of 24 family members had impaired hearing due to inner ear de

that hereditary nephritis is associated with hyperprolinemia and hyperaminoaciduria. A common transport system for renal tubular reabsorption is shared by the amino acids proline hydroxyproline and glycine according to these investigators This metabolic defect has been studied by other investigators particularly Minder & Dubach (8 57 66 67 74 82, 106) They observed hyperprolinemia in six of 21 siblings who were related to a known family with nephropathy Hyperaminoaciduria was found in eight of the 21 siblings. Methyl histidine excretion in the urine of family members was also noted by these authors They interpreted these findings as a mute" factor however probably indicating inheritance from one parent that occurred coincidentally in conjunction with the abnormal gene for nephropathy from the other parent One author has also reported amino-acidurias involving alanine glutamic acid histidine and threonine in the syndrome but no other confirmation of this could be located by the author (82)

Chappel stated that there were abnormalities in the alpha 2 fraction of the serum globulin but this was refuted in reports by others (1 51) No general metabolic error other than a possible enzyme system common to the kidney ear and eye has been identified Johnson points out the curious fact that the structures involved in this syndrome are those in which substance are concentrated against a gradient (kidney) or in which the contained fluids are not readily accessible to the systemic circulation (cochlear and lens) (2) Perhaps prospective studies in the future will be designed to permit tissue culture or analysis of kidney lens or cochlear fluids Such studies on tissue from affected patients might identify certain defective enzyme systems or abnormal toxin accumulations.

Temporal Bone Pathology

A complete histological study of the inner ear changes in hereditary hearing loss and nephropathy was not reported until late in 1968 (5) Winter and his co-workers obtained the temporal bones on a 22 year-old white male who died with the syndrome and who gave a history of hearing loss extending back to age 12 and of albuminuria documented at age 5 years The patient was approaching a terminal state and had severe loss of hearing for middle frequencies primarily Bilateral anterior lenticonus was found Winter was struck by the minimal changes on the temporal bone sections The tectorial membrane organ of Corti, and Reissner's membrane all were normal There was vesicle formation in the spiral ligament of each basal turn and some degeneration of the spiral nerves supplying the basal turns with approximately 50% reduction in basal turn spiral ganglion cells. Similar vesicle formation was noted under each utricular macule Both temporal bones were essentially identical as were the audiograms recorded nine months prior to death

These findings are probably the classic temporal bone changes of the syndrome because a similar pathologic picture was recorded in the post-mortem report of two of three brothers dying of the syndrome by Minder & Dubach in 1965 (74) Professor Nager of Zurich who performed the temporal bone examination on the two cases also recorded an atrophy of the spiral ganglion cells in the basal turns. More complete histological or audiometric information is not available in this report

Perkoff submitted the temporal bones in one of his cases to Victor Goodhill for sectioning but Goodhill recorded that cellular detail was poor and adequate evaluation of the organ of Corti was not possible No distinct histological abnormalities were noted Hyperostosis at the tip of the cochlea was men-

tioned but the patient was a 62-year-old female (7) None of these reports make mention of any inflammatory disease of the middle ear or mastoid.

Obviously only a sparce auditory-pathological correlation has been made in the syndrome and a distinct effort is needed on the part of otologists to obtain properly prepared temporal bones for study The author is now following a number of patients with the disease and has contacts with one large family that will hopefully cooperate for post-mortem study The three kindred reported in Part II of this paper are located in another state than that where the author currently practices and are not readily accessible. These findings are probably the classic tem poral bone changes of the syndrome because a similar pathologic picture was recorded in the post-mortem report of two of three brothers dying of the syndrome by Minder & Dubach in 1965 (74) Professor Nager of Zurich who performed the temporal bone examination on the two cases also recorded an atrophy of the spiral ganglion cells in the basal turns. More complete histological or audiometric informa tion is not available in this report

Perkoff submitted the temporal bones in one of his cases to Victor Goodhill for sec tioning but Goodhill recorded that cellular detail was poor and adequate evaluation of the organ of Corti was not possible No distinct histological abnormalities were noted Hy perostosis at the tip of the cochlea was men

and states that if the anterior capsule is weak a lenticonus develops but if it is deficient, a type of anterior polar cataract is formed. Thus, these two abnormalities seen in the hearing loss and nephropathy syndrome probably represent two stages of the same defect. The occurrence of spherophakia may also be a further stage of the same process since it is presumably due to a defect in the zonule (37)

Junod (65) and Ohlsson (82) in 1963 mention myopia as being a part of the ophthalmologic defects, and this seems to have been confirmed by a six year survey of 476 family members reported in 1965 (1) Tiliakos in his review of a Greek family noted one case of strabismus and one of pigmented retinitis. No recordings of lenticonus were noted (40) White punctate lesions in the fundus were recorded by Bunge in 1965 (39) It is likely that pigmentary changes noted in the syndrome are incidental. Cataracts are mentioned regularly in the family reviews listed in Table I. Dyschromatopsia was recorded in a Belgium family in 1966 (48) Perrin in 1964 did very careful ophthalmologic screening of 238 family members. He recorded alterations in the shape of the lens such as micospherophakia, anterior and posterior lenticonus, alterations in the transparency of the lens, anterior polar cataracts, subcapsular anterior or posterior cataracts nuclear cataracts and thickening of the central and anterior layers of the cornea accompanied by nystagmus. He recommended that slit-lamp and fundus examination be performed on family members (38) Another author commented on retrocorneal spindle shaped deposits in two cases of the syndrome (50) The latest eye report by Arnott in the British Journal of Ophthalmology again describes the finding of anterior lenticonus (42) The classic case studied histologically by Winter also had lenticonus (5)

Apparently fully-developed or advanced cases of the disease will manifest lens abnormalities and these may be related more to the chronic renal disease than to a hereditary anomaly If a genetic metabolic error does predispose the lens to poor fluid exchange or to toxic deposition, then the defect should probably be considered primary The author could not document any instances of lenticonus in his 54 family members reported in Part II. One coloboma was noted, and several refractive errors were recorded but not investigated because of inadequate eye preparation.

fect (74) Later they concluded that the nerve deafness in the family ran about 16–20% with an incidence of renal disease of 29% (8)

Certainly young children may have the sensorineural hearing loss although it usually becomes manifest in the second decade in the male and later in the female One French report even mentions nerve deafness beginning in infancy (72) Modern infant audiometry does permit testing at this age with reliable results.

Sohar mentioned that recruitment was present in two of his cases with sensorineural loss in 1954 (34) Goldbloom recorded normal dorsal and ventral cochlear nuclei and tracts in his study of a case in 1957 (60) Klotz documented the air and bone conduction levels in a case studied over a two-year interval Further decline in hearing for all frequencies 256 to 8 192 cps was recorded (4) Johnson performed audiometry on several family members of a kindred in 1965 and stated that the pure tone curves were of two types. One was a descending curve with loss of hearing more severe in the high frequencies The other type manifested a drop at 4 096 cps. He did not list the number of examinations done nor the conditions of testing Speech testing and discrimination scores were recorded in twin boys age 17 and 18 One also had positive SISI scores at 500 and 2 000 cps and a Type II Bekesy tracing (2) This was strong evidence for the presence of a cochlear lesion rather than a retrocochlear one Suzuki documented a case from Japan exhibiting recruitment with normal vestibular function tests and normal petrous apex films (6)

The hearing pattern of the histologically verified case of Winter included a moderate loss for pure tones (range 30–65 dB ASA), slight discrimination loss and normal SISI scores Temporal bone pathology showed 50% loss of spiral ganglion cells in the basal turns (5)

In 1955 Poli called attention to the unusually high incidence of severe otitis media in the syndrome (85) and this finding has been recorded by other investigators (1 82) The author encountered a number of ear drum scars and distortions in his examinations reported in Part II However not a single perforation was noted. Several ear drum retractions were seen indicating Eustachian tube malfunction and negative Rinne tests were recorded for 256 and 512 cps in these patients. Perhaps greater attention should be given to recording a history of ear infections when female members with the syndrome were examined. The primary value would seem to lie in differentiating family suspects with hearing loss who might be erroneously labeled with the disease unless the conductive nature of the hearing loss was recognized As mentioned under temporal bone pathology none of the three reported histological examinations made any mention of inflammatory disease or residue in the middle ear

Ocular Abnormalities

Since the notation by Sohar in 1954 of spherophakia and cataracts, more careful attention has been paid to the identification of ophthalmologic disorders Anterior subcapsular cataracts were discovered in one family member by Goldbloom in 1957 (60) Mention was made of congenital abnormalities of the eyes in a report by Reyersbach & Butler in 1954 but no specific descriptions were given (91) Chappel mentioned lens deformities and alpha 2 globulin disturbances in his report in 1960 (51) Two detailed cases of lenticonus were described by Mettier in 1961 and one patient had a retinal detachment The detachment was considered to be incidental. Mettier describes the pathogenesis of the abnormalities,

and states that if the anterior capsule is weak a lenticonus develops but if it is deficient, a type of anterior polar cataract is formed. Thus, these two abnormalities seen in the hearing loss and nephropathy syndrome probably represent two stages of the same defect. The occurrence of spherophakia may also be a further stage of the same process since it is presumably due to a defect in the zonule (37).

Junod (65) and Ohlsson (82) in 1963 mention myopia as being a part of the ophthalmologic defects, and this seems to have been confirmed by a six year survey of 476 family members reported in 1965 (1). Tiliakos in his review of a Greek family noted one case of strabismus and one of pigmented retinitis. No recordings of lenticonus were noted (40). White punctate lesions in the fundus were recorded by Bunge in 1965 (39). It is likely that pigmentary changes noted in the syndrome are incidental. Cataracts are mentioned regularly in the family reviews listed in Table I. Dyschromatopsia was recorded in a Belgium family in 1966 (48). Perrin in 1964 did very careful ophthalmologic screening of 238 family members. He recorded alterations in the shape of the lens such as micospherophakia, anterior and posterior lenticonus, alterations in the transparency of the lens, anterior polar cataracts subcapsular anterior or posterior cataracts, nuclear cataracts and thickening of the central and anterior layers of the cornea accompanied by nystagmus. He recommended that slit-lamp and fundus examination be performed on family members (38). Another author commented on retrocorneal spindle-shaped deposits in two cases of the syndrome (50). The latest eye report by Arnott in the British Journal of Ophthalmology again describes the finding of anterior lenticonus (42). The classic case studied histologically by Winter also had lenticonus (5).

Apparently fully-developed or advanced cases of the disease will manifest lens abnormalities and these may be related more to the chronic renal disease than to a hereditary anomaly. If a genetic metabolic error does predispose the lens to poor fluid exchange or to toxic deposition, then the defect should probably be considered primary. The author could not document any instances of lenticonus in his 54 family members reported in Part II. One coloboma was noted, and several refractive errors were recorded but not investigated because of inadequate eye preparation.

PART II

The Audiometric Survey

In 1959 particular attention was drawn to the hereditary syndrome of hearing loss and nephropathy at our medical center because of a specific interest on the part of several internists in more accurately delineating renal pathology thought to be pathognomic of the disorder (102) Once several patients with possible hereditary nephropathy were identified then a concerted effort was made to evaluate relatives who might be affected Three separate kindred who were geographically accessible to the medical center were identified over a period of three years and a survey was made to obtain urinalyses, hearing tests otologic evaluations and screening eye examinations

A large number of individuals of each kindred were contacted but only a small number could be reached for audiometric screening or persuaded to visit the hospital for specific examination There were 216 members identified in the first kindred 233 in the second, and 140 in the third Screening audiograms were taken in the field by another examiner on 92 of this total number From this group of 92 family members representing an age range of 2 to 65 years, 56 individuals visited the hospital clinics for controlled, identical audiometric testing and otologic examinations All members were encouraged to attend but many could not conveniently come therefore the selection of patients was randomized on the basis of volunteers A comparison of the screened with the examined group indicates that a valid sample of each age group volunteered for more exact testing Very few children under five years of age were contacted Audiometric results in the very young would probably be normal since other authors have indicated (1 5 7 100 101 103) that individuals affected with the full or partial syndrome have shown a progressive loss as the renal disease increases in its severity The common occurrence of serous otitis media in the age group under five years would probably complicate specific identification of hearing losses as would the testing techniques of bone conduction In addition there were only two children screened in the age group 0–4 years one 2 years old and one 4 years old thus the numerical loss from the total group studied is quite small. Table II shows a comparison of screened with examined family members

The three kindred studied all live in a single southern state and are of Anglo-Saxon descent. The families were largely settled in limited geographic areas within the state and family relationships are well-known Knowledge of the geneology permitted pedigree recordings as far back as five generations in two families and six generations in the other The pattern of the disease based on available urologic and otologic testing is recorded in Charts I II and III A clinical history of hearing impairment rather than direct testing was used by interviewers to designate some family members as being af

PART II

The Audiometric Survey

In 1959 particular attention was drawn to the hereditary syndrome of hearing loss and nephropathy at our medical center because of a specific interest on the part of several internists in more accurately delineating renal pathology thought to be pathognomic of the disorder (102) Once several patients with possible hereditary nephropathy were identified then a concerted effort was made to evaluate relatives who might be affected Three separate kindred who were geographically accessible to the medical center were identified over a period of three years and a survey was made to obtain urinalyses hearing tests otologic evaluations and screening eye examinations.

A large number of individuals of each kindred were contacted but only a small number could be reached for audiometric screening or persuaded to visit the hospital for specific examination There were 216 members identified in the first kindred 233 in the second and 140 in the third Screening audiograms were taken in the field by another examiner on 92 of this total number From this group of 92 family members representing an age range of 2 to 65 years, 56 individuals visited the hospital clinics for controlled identical audiometric testing and otologic examinations. All members were encouraged to attend but many could not conveniently come, therefore the selection of patients was randomized on the basis of volunteers. A comparison of the screened with the examined group indicates that a valid sample of each age group volunteered for more exact testing Very few children under five years of age were contacted Audiometric results in the very young would probably be normal since other authors have indicated (1 5 7 100 101 103) that individuals affected with the full or partial syndrome have shown a progressive loss as the renal disease increases in its severity The common occurrence of serous otitis media in the age group under five years would probably complicate specific identification of hearing losses as would the testing techniques of bone conduction In addition, there were only two children screened in the age group 0–4 years, one 2 years old and one 4 years old thus the numerical loss from the total group studied is quite small Table II shows a comparison of screened with examined family members.

The three kindred studied all live in a single southern state and are of Anglo-Saxon descent. The families were largely settled in limited geographic areas within the state and family relationships are well known Knowledge of the geneology permitted pedigree recordings as far back as five generations in two families and six generations in the other The pattern of the disease based on available urologic and otologic testing is recorded in Charts I II and III A clinical history of hearing impairment rather than direct testing was used by interviewers to designate some family members as being af

initial routine otolaryngology examination was performed which included inspection of the pharynx and nasopharynx, transillumination of the frontal and maxillary sinuses, palpation of the neck and otoscopic evaluation of the external auditory canal and tympanic membrane with a pneumatic otoscope. Tuning fork testing with 256 and 512 cps steel forks was performed and results of the Rinne and Weber tests were recorded. If a difference in hearing between air and bone conducted sound was identified to either of these two forks then carefully masked bone audiometry was performed. Fork testing was performed in an *Industrial Acoustics sound room with the door* ajar Pure tone testing and bone audiometry was performed with the door closed and with an attenuation in decibels of 54 at 4800–10 KC. Unilateral airbone gaps were tested by fork with a Barany noise maker masking the opposite car Bone conduction audiometry was performed with a head-band, light weight mastoid attenuator Masking was accomplished with a saw-toothed noise-maker at 40 dB above threshold Testing was carried out with a Beltone 14–A audiometer in a two-room setting with the patient under direct observation The audiometer was calibrated according to American Standards Association 1951 levels and charts were prepared using these values as *reference standards. Frequencies between 256* and 8 192 cps were tested The same instruc

tions were given to each patient and each responded with a hand signal. Test tones were presented in an ascending fashion going from silence up to threshold using a pulsed tone for both air and bone signals. Each threshold was checked by testing the next lowest intensity level at least twice. An average response was not obtained but the intensity recorded represented the response given on at least two of the three trials. A single response not reproducible at least twice, was not used as threshold.

The author attempted to obtain a hearing level which would be meaningful to physicians and audiologists encountering family members with the hereditary syndrome. Testing performed in an elaborate laboratory setting would not be as useful for future clinical evaluations, since their specific circumstances could not be approached in most clinics called upon to evaluate the patients. The apparatus and technique used by the author is generally available in almost all otolaryngology out-patient clinics, speech and hearing centers, and in many otologists offices, and the audiograms obtained can be compared with the "typical" tracings presented in this paper. Field screening results have definite limitations as indicated by Corso (11) and, therefore, the field results on the three kindred studied here are not included. Certainly "field" otolaryngology clinical evaluations are also of limited value.

A number of abnormalities were noted on inspection of the ear drum and the author obtained a number of differences in hearing by fork testing to air and bone which necessitated using bone conduction as a more accurate means of documenting the true level of sensorineural reserve. The author appreciates the limitations inherent in bone conduction but is of the opinion that a combination of controlled air and bone testing gives a more accurate picture of the true threshold of hearing than does either alone. In recording the audiometric findings, the level of masked bone conduction was used as the threshold if fork testing at 256 and 512 showed a negative Rinne. Otherwise the pure tone air conduction level was used as threshold.

Ear drums were evaluated for evidence of retraction, healed perforation, immobility, tympanosclerotic plaques, perforation, fluid, abnormal coloration, increased vascularization or operative scar. A careful search was made for any congenital malformations of the pinna, pre-auricular area, canal or upper neck area. Wax was carefully removed from the canal and care was taken to note any potential collapse of the canal with pressure on the tragus.

A screening slit-lamp exam was also carried out on each patient primarily to identify any lenticular abnormalities, since ocular abnormalities have been included as part of the syndrome since Sohar's report (34). An attempt was made to identify cataracts and lenticonus but no cases with these abnormalities were found. One patient had a coloboma and this was the only structural abnormality noted in the 56 patients. No attempt was made to map fundus changes although the fundus was checked in the majority of patients. Accurate fundoscopic evaluations require mydriatic drugs

and the author did not wish to subject volunteers to any potentially hazardous medications Mydriasis would also have permitted more exacting slit lamp exam but the evaluation performed was considered to be critical enough to rule out significant abnormalities Refractive errors were checked with a screening wall chart reading but again no accurate recording of myopia or hyperopia was made because of incomplete eye preparation There were only a few previously diagnosed eye abnormalities in the group and no new abnormalities were identified Tests for dyschromatopsia and intraocular tension were not carried out.

Analysis

The most striking finding in this survey of hearing responses is the paucity of audiometric changes even in those family members manifesting evidence of renal disease Although previous authors have demonstrated distinct sensorineural hearing changes in advanced cases of the hereditary syndrome as mentioned in Part I family members may have very minimal hearing changes and losses attributable to the syndrome may be more apparent than real if care is taken to eliminate other obvious causes of hearing loss particularly those of a conductive nature

Inspection of the groups divided by age and sex reveal a consistent drop at 6 000 cps in both the individual analyses and the average values This finding is not significant for all age groups however This change may be the result of some mechanical defect inherent in the testing apparatus the sound room or the application of the pure tone The author evaluated the first possibility by repeatedly testing volunteers with known audiometric patterns who were frequently used to check calibration of the audiometer No defect in the 6 000 cycle tone was identified An attempt was also made to perform some tests with the door of the sound room open Although other frequencies usually in the 500 cycle range were adversely affected there was no change with testing at 6 000 cps Perhaps the length of the ear canal and the impedance qualities of the ear drum may lead to the creation of a standing wave in the ear canal with a cancelling effect at low intensities of sound The author doubts that such a phenomenon could occur so consistently throughout the testing

In a study of 2891 otoscopically normal children ages 5–14 years Jordan & Eagles (109) indicated that both the median and mean sensitivity was the least at 6 000 cps and this poor sensitivity (higher threshold) continued to be noted in 82 otoscopically abnormal children with impaired mobility discoloration and retraction of the pars tensa This common finding of a drop at 6 000 cps in children under 15 years makes the author s recordings of a loss at 6 000 cps of no significance in this age group

According to the tables prepared by Corso on threshold data by age groups and sex the threshold is higher at 6 000 cps in the age groups 26–49 years for adult males and only in the age group 43–49 for females These data were obtained in otoscopically normal individuals age 18–65 years Since all age groups from 15–65 years in the families with the hereditary syndrome exhibited a drop at 6 000 cps, the finding would appear to be of significance for female individuals over 15 years of age except in the small group 43–49 years. The finding appears to be of minimal significance in the great majority of adult males since they exhibit a drop at 6 000 cps normally according to Corso As mentioned in Part I the hearing disorder is usually progressive in adolescence and young adults with findings in childhood usually normal When this fact is correlated with the audiometric-otological survey of 54 family members, then the value

of the audiometer in identifying potential cases of the syndrome becomes apparent.

Controlled audiometry should probably be performed on all females with evidence of renal dysfunction or with a family history of renal disease. An isolated drop at 6 000 cps should alert the examiner to potential existance of the hereditary syndrome. All females being considered as renal transplant donors should have controlled audiometry in conjunction with a careful otological examination. Because of the aggressive nature of the disease in males, virtually all male patients will have overt signs of renal disease and probably hearing loss after the age of 15 years. Audiometry in these patients will have supplemental value primarily. Audiometric screening should probably be done routinely on adolescent male relatives of patients with the hereditary syndrome, however, in order to identify unknown cases of the syndrome.

The normal finding of decreased hearing sensitivity at 6 000 cps when compared to other frequencies in the age group under 15 years by Jordan and Eagles seems to rule against the virtue of audiometric screening in this age group.

Earlier identification and recognition of the syndrome may permit the salvage of some males with renal transplantation before extensive protein loss and toxemia develop. Earlier identification of the hearing pattern *before* ototoxic drugs have been given for presumed or associated nephritis will aid proper diagnosis of the hereditary syndrome also.

Very little is known of the histological changes in the temporal bone except in two documented cases mentioned previously (5, 74). Internists and pediatricians treating renal disease as well as urologists should be alerted to this gap in our scientific knowledge and encouraged to refer children and young adults with any renal dysfunction for serial audiometry at least yearly and more frequently if a rapidly progressive disorder is present. Otolaryngologists should make a personal effort to secure the temporal bones on these patients. Renal biopsy and renal tissue culture should be encouraged also.

A general susceptibility of kidney disorders may indeed be an inherited phenomenon in the vast majority of renal disease patients. The amino-aciduria mentioned under metabolic patterns may represent an enzymatic transport defect in one organ that perhaps exists in another and by histiochemical studies of renal tissue cultures a better identification of biochemical processes in the sensorineural elements of the ear may be possible. Structure and function must be correlated, however, and only with wide acceptance of controlled audiometry can adequate pre-biopsy, pre-culture and pre-autopsy information be obtained.

New family reports of the deafness and nephropathy syndrome are appearing in the medical literature each year as greater acceptance of the concept of hereditary nephritis occurs. Perhaps the tragic course of the disease in the male can be averted if renal transplant or preventive drugs are used. Certain drugs *have recently* been introduced which protect the ear against the ototoxicity of streptomyces-antibiotics (111) and certain methyl-donor containing amino acids may protect the kidney against nephrotoxic drugs (110). Early identification of the syndrome may permit trial of these substances in hereditary nephritis where a membrane reabsorption defect may exist *similar* to that created by ototoxic drugs.

Summary

The syndrome of hereditary deafness with nephropathy is reviewed and detailed audiometric data in 54 family members of three separate kindred is presented. Controlled au-

and the author did not wish to subject volunteers to any potentially hazardous medications Mydriasis would also have permitted more exacting slit-lamp exam but the evaluation performed was considered to be critical enough to rule out significant abnormalities Refractive errors were checked with a screening wall chart reading but again no accurate recording of myopia or hyperopia was made because of incomplete eye preparation There were only a few previously diagnosed eye abnormalities in the group and no new abnormalities were identified Tests for dyschromatopsia and intraocular tension were not carried out.

Analysis

The most striking finding in this survey of hearing responses is the paucity of audiometric changes even in those family members manifesting evidence of renal disease Although previous authors have demonstrated distinct sensorineural hearing changes in advanced cases of the hereditary syndrome as mentioned in Part I family members may have very minimal hearing changes and losses attributable to the syndrome may be more apparent than real if care is taken to eliminate other obvious causes of hearing loss particularly those of a conductive nature

Inspection of the groups divided by age and sex reveal a consistent drop at 6 000 cps in both the individual analyses and the average values. This finding is not significant for all age groups however This change may be the result of some mechanical defect inherent in the testing apparatus, the sound room or the application of the pure tone The author evaluated the first possibility by repeatedly testing volunteers with known audiometric patterns who were frequently used to check calibration of the audiometer No defect in the 6 000 cycle tone was identified An attempt was also made to perform some tests with the door of the sound room open. Although other frequencies usually in the 500 cycle range were adversely affected there was no change with testing at 6 000 cps Perhaps the length of the ear canal and the impedance qualities of the ear drum may lead to the creation of a standing wave in the ear canal with a cancelling effect at low intensities of sound The author doubts that such a phenomenon could occur so consistently throughout the testing.

In a study of 2891 otoscopically normal children ages 5–14 years Jordan & Eagles (109) indicated that both the median and mean sensitivity was the least at 6 000 cps and this poor sensitivity (higher threshold) continued to be noted in 82 otoscopically abnormal children with impaired mobility discoloration and retraction of the pars tensa This common finding of a drop at 6 000 cps in children under 15 years makes the author s recordings of a loss at 6 000 cps of no significance in this age group

According to the tables prepared by Corso on threshold data by age groups and sex the threshold is higher at 6 000 cps in the age groups 26–49 years for adult males and only in the age group 43–49 for females These data were obtained in otoscopically normal individuals age 18–65 years Since all age groups from 15–65 years in the families with the hereditary syndrome exhibited a drop at 6 000 cps, the finding would appear to be of significance for female individuals over 15 years of age except in the small group 43–49 years. The finding appears to be of minimal significance in the great majority of adult males since they exhibit a drop at 6 000 cps normally according to Corso As mentioned in Part I the hearing disorder is usually progressive in adolescence and young adults with findings in childhood usually normal. When this fact is correlated with the audiometric-otological survey of 54 family members, then the value

of the audiometer in identifying potential cases of the syndrome becomes apparent.

Controlled audiometry should probably be performed on all females with evidence of renal dysfunction or with a family history of renal disease. An isolated drop at 6 000 cps should alert the examiner to potential existance of the hereditary syndrome. All females being considered as renal transplant donors should have controlled audiometry in conjunction with a careful otological examination. Because of the aggressive nature of the disease in males virtually all male patients will have overt signs of renal disease and probably hearing loss after the age of 15 years. Audiometry in these patients will have supplemental value primarily. Audiometric screening should probably be done routinely on adolescent male relatives of patients with the hereditary syndrome, however, in order to identify unknown cases of the syndrome.

The normal finding of decreased hearing sensitivity at 6 000 cps when compared to other frequencies in the age group under 15 years by Jordan and Eagles seems to rule against the virtue of audiometric screening in this age group.

Earlier identification and recognition of the syndrome may permit the salvage of some males with renal transplantation before extensive protein loss and toxemia develop. Earlier identification of the hearing pattern *before* ototoxic drugs have been given for presumed or associated nephritis will aid proper diagnosis of the hereditary syndrome also.

Very little is known of the histological changes in the temporal bone except in two documented cases mentioned previously (5, 74). Internists and pediatricians treating renal disease as well as urologists should be alerted to this gap in our scientific knowledge and encouraged to refer children and young adults with any renal dysfunction for serial audiometry at least yearly and more frequently if a rapidly progressive disorder is present. Otolaryngologists should make a personal effort to secure the temporal bones on these patients. Renal biopsy and renal tissue culture should be encouraged also.

A general susceptibility of kidney disorders may indeed be an inherited phenomenon in the vast majority of renal disease patients. The amino-aciduria mentioned under metabolic patterns may represent an enzymatic transport defect in one organ that perhaps exists in another and by histiochemical studies of renal tissue cultures a better identification of biochemical processes in the sensorineural elements of the ear may be possible. Structure and function must be correlated, however, and only with wide acceptance of controlled audiometry can adequate pre-biopsy, pre-culture, and pre-autopsy information be obtained.

New family reports of the deafness and nephropathy syndrome are appearing in the medical literature each year as greater acceptance of the concept of hereditary nephritis occurs. Perhaps the tragic course of the disease in the male can be averted if renal transplant or preventive drugs are used. CONTENTS

Foreword

In current practice the ear specialist often finds it necessary to establish whether or not a child's hearing capacity is handicapped.

Generally such examination is requested by children's parents or teachers who have noticed a possible retarded phonation or more-or-less pronounced speech disorders. At times the symptomatology of these small patients may appear more complex since as well as phonation disturbances they display an impairment of psycho-intellectual capacity or disorders in locomotor-apparatus functioning, or deficiencies in other sensorial apparata as well as hearing, or yet an association of several of these disorders. Clearly in such conditions audiometric research can become particularly complicated, and the audiologist must be aided in his investigation by the psychologist, neurologist, pediatrician, by a whole team of co-workers, enabling him to give the clinical case a precise framework.

Our work aims at contributing to knowledge of the audiometric techniques based on the study of conditioned reflexes.

In our view these methods of investigation are of considerable interest, since (a) they often achieve particularly satisfying results, as data in the literature show (b) they involve using relatively simple and thus inexpensive equipment and (c) they enable the hearing capacity of patients to be ascertained in the course of consultancy investigation, that is as outpatients without need for admittance or for administering hypnotics or anaesthetics.

In view of this we thought it expedient to make a comparative study as to the usefulness of the various methods of audiometric investigation based on conditioned reflexes, put forward by previous researchers, with a view to establishing the advantages each has over the others (also in relation to the age of examined subjects and their neurological and psycho-intellectual as well as hearing handicaps) and acquiring more thorough knowledge of them and possibly making them easier to implement.

In our survey we took into account 316 subjects whose ages varied from 1 to 5 years.

It is to be pointed out first of all that our cases always displayed such behavioural reactions as to lead to suspicion of a possible hearing impairment, thereby warranting audiometric examination.

Specifically these were subjects displaying the following isolated or variously associated disorders.

(i) More-or-less severe hearing deficiency
(ii) Retardation or rather alterations to varying extent in speech.
(iii) Neurological disturbances associated with low I.Q.

In view of the clinical characteristics of the patients examined, our statistical data can be compared with those of Authors who have only studied normal individuals with proper caution, allowing for the greater difficulties we ourselves encountered.

Our cases were subjected to audiometric investigation, and based upon study either of (a) psychogalvanic reflex, or (b) conditioned instrumental reflexes, or (c) conditioned orientation reflexes.

All patients were examined by at least two of these techniques, with a view to confirming and integrating the data obtained with each method of investigation.

In a separate appendix to this work we further study and discuss the validity of the

above audiometric techniques for determining the hearing capacity of patients who are particularly complex from a clinical viewpoint

These were cases where, owing to the simultaneous presence of lesions to various sensorial apparata or the existence of severe neurological or psycho-intellectual handicaps, the audiometric examination presented unquestionable difficulties

The data on these cases, though not sufficiently numerous to permit statistical considerations, nevertheless contribute to knowledge of the possibilities and limitations of the audiometric techniques taken into account by us.

We must point out, lastly that all the subjects were studied during consultancy-type investigations, and thus without admitting them. In some more complicated cases, however it was necessary to repeat and complete the examination in subsequent sessions, at an interval of hours or even days between each. In doing this we always allowed for the fact that in infant audiometric investigations it is advisable to avoid tiring or irritating the subject if one wants his full co-operation, and hence more accurate data.

CHAPTER 1

Psychogalvanic or Electrodermal Reflex

1 PREVIOUS RESEARCHES

(a) Physiological premises

In 1888 Féré first discovered that skin resistance to the passage of electric current underwent changes as a result of emotive phenomena or sensorial excitation of varied nature These changes could be measured accurately by a milliampermeter Féré called the phenomenon Psychogalvanic Reflex (P G.R.).

Several theories have been put forward by different Authors to explain this typical reflex reaction: lowered skin resistance as a result of an emotive stimulus of varying nature has been related to changes in sweat-gland secretion (Darrow 1934) as well as to variations in local circulation (Goadby & Goadby) But the possibility that reactions of the muscular fibres interfere with the mechanisms whereby P G R. is governed has been ruled out (Duret-Cosyns & Duret)

The changes in sweat-gland secretion and consequent variations in skin *electrical* resistance, which arise as a result of emotive phenomena of varying nature are unquestionably secondary to neurovegetative reflexes by stimuli which according to the majority of Authors, run mainly in the sympathetic fibres. Wells & Forbes have however uphold possibility that a certain number of these stimuli also follow the parasympathetic fibres.

Various investigations have been carried out to establish what the physiological phenomena are that govern P G.R., and principally what nerve centres condition and regulate its appearance

According to some researchers (Wang & Lu, 1930 Wang & Mok Darrow 1934 Spiegel & Hunsicher Swartz) this reflex depends on the activity of the cerebral cortex and, in particular on that of the premotor area. Others (Kennard Craig & Hare) would have it that they are under the control of subcortical and specifically thalamic centres.

The first hypothesis seems to find wider consensus.

In this connection Duret-Cosyns & Duret conducted investigations demonstrating that central perception of the stimulus by the subject is an essential element for the onset of P G R. sleep, narcosis, coma and interruption of the *sensitive fibres of the* stimulated area in fact nullify any response whatever characteristic the stimulus may have

Studies on P.G.R. have taken on particular importance especially from the clinical viewpoint, since Bordley Hardy & Richter in 1948 thought of using this reflex to establish the hearing capacity of a subject not referring to his own responses (subjective audiometry) but to objective data directly detectable by the examiner and uninfluenced by the subject s greater or lesser degree of co-operation. These researchers first of all found that a sudden auditory stimulus with intensity of at least 40 dB above threshold could in fact cause the onset of P G R. But this reflex is scarcely utilizable for practical purposes indeed, besides having a particularly high intensity the auditory stimulus must reach the subject suddenly so as to provoke an emotive reaction of some entity Moreover this reaction exhausts easily when

These were cases where owing to the simultaneous presence of lesions to various sensorial apparata or the existence of severe neurological or psycho-intellectual handicaps the audiometric *examination presented unquestionable* difficulties

The data on these cases, though not sufficiently numerous to permit statistical considerations, nevertheless contribute to knowledge of the possibilities and limitations of the audiometric techniques taken into account by us.

We must point out, lastly that all the subjects were studied during consultancy-type investigations, and thus without admitting them. In some more complicated cases, however it was necessary to repeat and complete the examination in subsequent sessions, at an interval *of hours or even days between each In doing* this we always allowed for the fact that in infant audiometric investigations it is advisable to avoid tiring or irritating the subject if one wants his full co-operation and hence more accurate data.

Psychogalvanic or Electrodermal Reflex

1 PREVIOUS RESEARCHES

(a) Physiological premises

In 1888 Féré first discovered that skin resistance to the passage of electric current underwent changes as a result of emotive phenomena or sensorial excitation of varied nature These changes could be measured accurately by a milliampermeter Féré called the phenomenon Psychogalvanic Reflex (P G.R.)

Several theories have been put forward by different Authors to explain this typical reflex reaction. lowered skin resistance as a result of an emotive stimulus of varying nature has been related to changes in sweat-gland secretion (Darrow 1934) as well as to variations in local circulation (Goadby & Goadby) But the possibility that reactions of the muscular fibres interfere with the mechanisms whereby P G.R. is governed has been ruled out (Duret-Cosyns & Duret)

The changes in sweat-gland secretion and consequent variations in skin electrical resistance which arise as a result of emotive phenomena of varying nature, are unquestionably secondary to neurovegetative reflexes by stimuli which, according to the majority of Authors, run mainly in the sympathetic fibres Wells & Forbes have however uphold possibility that a certain number of these stimuli also follow the parasympathetic fibres.

Various investigations have been carried out to establish what the physiological phenomena are that govern P G R., and principally what nerve centres condition and regulate its appearance

According to some researchers (Wang & Lu, 1930 Wang & Mok Darrow 1934 Spiegel & Hunsicher Swartz), this reflex depends on the activity of the cerebral cortex and, in particular on that of the premotor area. Others (Kennard Craig & Hare) would have it that they are under the control of subcortical and specifically thalamic centres.

The first hypothesis seems to find wider consensus.

In this connection Duret-Cosyns & Duret conducted investigations demonstrating that central perception of the stimulus by the subject is an essential element for the onset of P G.R. sleep, narcosis, coma and interruption of the sensitive fibres of the stimulated area in fact nullify any response, whatever characteristic the stimulus may have

Studies on P G.R. have taken on particular importance, especially from the clinical viewpoint, since Bordley Hardy & Richter in 1948 thought of using this reflex to establish the hearing capacity of a subject not referring to his own responses (subjective audiometry) but to objective data directly detectable by the examiner and uninfluenced by the subject s greater or lesser degree of co-operation. These researchers first of all found that a sudden auditory stimulus with intensity of at least 40 dB above threshold could in fact cause the onset of P G.R. But this reflex is scarcely utilizable for practical purposes, indeed, besides having a particularly high intensity the auditory stimulus must reach the subject suddenly so as to provoke an emotive reaction of some entity Moreover this reaction exhausts easily when

above audiometric techniques for determining the hearing capacity of patients who are particularly complex from a clinical viewpoint

These were cases where, owing to the simultaneous presence of lesions to various sensorial apparata or the existence of severe neurological or psycho-intellectual handicaps the audiometric examination presented unquestionable difficulties

The data on these cases though not sufficiently numerous to permit statistical considerations nevertheless contribute to knowledge of the possibilities and limitations of the audiometric techniques taken into account by us.

We must point out, lastly that all the subjects were studied during consultancy-type investigations, and thus without admitting them. In some more complicated cases, however it was necessary to repeat and complete the examination in subsequent sessions at an interval of hours or even days between each In doing this we always allowed for the fact that in infant audiometric investigations it is advisable to avoid tiring or irritating the subject if one wants his full co-operation and hence more accurate data

such tender age to understand the mechanism of play audiometry

Conversely Borel-Maisonny observed differences at times more than 40–50 dB for the various frequencies in children aged between 3 and 6

Pellegrini revealed threshold differences of over 30 dB in children under 3 years of age, while these fluctuated between 5 and 20 dB in adults

Pesavento, on the basis of a case-list of 56 children with ages varying from 2 to 5 years, was able to establish the following:

(*a*) P G R. study achieves threshold values generally corresponding with considerable approximation to those obtained by using the Peep-show (cf instrumental conditioned reflexes—Page 17)

(*b*) In children aged between 3 and 5 the threshold values found by P G R. study can be about 10 dB above the real

(*c*) In children between 2 and 3 years of age audiometry by way of P G R. study is sometimes the only practicable investigation method even though it often gives threshold values higher than the real—the error may be as much as 20–25 dB above real threshold.

Sortini studied 250 preschool-age children and reported having satisfactorily assessed the hearing in all cases through P G R. examination He was able to discuss the possibility of phonetic training in 174 cases on the basis of the data so obtained

Germanà sought the hearing threshold for 6 frequencies (250, 500 1 000, 2 000 3 000 and 4 000 c s) in 20 children aged between 6 and 13 attending a School for the Deaf in order to highlight any residue exploitable for speech-auditory training He made a comparative study of the audiometric curves drawn from subjective tone audiometry and P G.R. study In the latter the threshold was higher in every case the difference in curves obtained by the two methods varied *from 5 to 25 dB*, and was always more sensitive in *younger subjects*, especially in the acute-frequency range.

Barr who investigated 20 adults, found no significant difference between threshold values obtained through P G.R. study and by tone audiometry

Dupon-Tersen affirmed the importance of audiometry through P G.R. study in the case of 2 and 3-year-old children. He pointed out, however that this method can give rise to errors in these subjects, since a threshold 30–40 dB higher than the real is always obtained Consequently judgment as to the possibilities of training them cannot be based solely upon data drawn from this examination.

Lüscher & Kusen researched on three groups of subjects whose ages ranged from 6 to 60 and detected very slight differences between threshold values obtained through P G.R. study and from using the peep-show or classical tone audiometry The threshold by the former method was in fact always higher than the real. The difference fluctuated between 0 and 20 dB in the control group of 15 normal-hearing subjects, 0 and 10 dB in the group of 26 hard-of hearing subjects aged between 6 and 60 and in the one comprising 23 deaf-mutes with ages ranging from 7 to 16 In some cases these differences could however be higher reaching 30 dB The Authors conclude that the reliability of audiometric values obtained through P G.R. study is considerably greater in impaired-hearing than in normal-hearing subjects.

Grisanti *(1958) studied* the ratio between hearing threshold obtained through simple, i.e., unconditioned, P.G.R. study and by subjective tone audiometry He detected an average difference fluctuating between 20 and 45 dB But this deviation would be appreciably increased in correspondence with the acute frequencies. Grisanti related this phenomenon to the lower emotive capacity of these frequencies

Baron & Dejour subjected to control by classical tone audiometry 25 children previously examined by P G R. over a period of 10 years. They reported that in the majority of children —aged between 1 ½ and 4 at the time of first examination—the control substantially confirmed, with a threshold difference varying from 10 to 15 *dB*, the audiometric curves defined

the examination is prolonged, and it is hardly possible to define the subject's audiogram under such conditions Bordley et al then thought of conditioning P G R. on the principles substantiated by Pavlov's observations More specifically they proceeded as follows routing an auditory stimulus of surely supraliminal intensity and after a few seconds a slightly painful electric shock The latter brought about the onset of obvious P G.R. These stimulations were repeated a certain number of times It was observed at a given moment that the sound stimulus caused P G R. to make its appearance even though it was not followed by the pain stimulus At this moment the patient could be regarded as conditioned any sound stimulus, even of intensity slightly above threshold, could bring about the appearance of P G R.

(*b*) Determining the hearing threshold through study of psychogalvanic reflex

The Bordley Hardy & Richter experiments were later taken up by numerous Authors who used conditioned P G R in studying the hearing capacity under different clinical and experimental conditions, and in particular for determining the hearing threshold in children. These researches could be conducted by using appropriately designed devices (psychogalvanometers) These afford a graphic recording where in the stimuli routed to the subject and changes in his skin resistance due to the psychogalvanic reflex are given

Bordley Hardy & Richter as well as Authors who later dealt with the subject first attempted *to establish whether the hearing threshold determined* through P G R study tallied approximately *enough with the* one detected by classical tone audiometry

It is to be noted in this regard that the results of researches conducted by these Authors on adults or school age children are fairly in agreement and demonstrate that objective audiometry based on P G R. study achieves sufficiently reliable data on the hearing threshold

Bordley & Hardy studied 700 subjects in this connection They achieved positive results in *95% of examined cases More specifically* they observed an average difference between the *hearing threshold* by *classical tone audiometry* and the one obtained through P G R. study of 2.46 dB in adults and 3 60 *dB in children aged* between 4 and 14

Maspétiol Gourgerot & *Konne revealed that* the threshold obtained through P G.R. study was higher (and thus the hearing loss more severe) than that drawn from conventional tone audiometry by 10–20 dB in adults and children over 8 years of age This difference rose to 15–25 dB in subjects aged between 4 and 8 to 20–30 dB in 3–4-year-olds and 30–40 dB in 2–3 year-olds These Authors also pointed out the frequency of failures in subjects under 3 years of age

Conversely Faure, Portmann, Dutertre & Bramerie observed that the threshold differences in adults were contained to within 2 and 3 dB but they rose to 10 dB in subjects aged between 4 and 7 to 15–20 dB in 2 1/2- to 4-year-olds and to 20–30 dB in those under 2 1/2.

According to Pagano who studied children aged between 4 and 7 the difference between the threshold obtained by examinations via P G R study and the one detected by classical tone audiometry does not exceed 10–15 dB

Doeffler & McClure examined 30 adult subjects and detected *an average difference* of 3 50 dB between the threshold by traditional tone *audiometry and the one* obtained through P G R. study

Barr performed examinations on 324 children aged between 1 and 6 In subjects over 2 1/2 years of age he obtained in 85% of cases threshold values with P G R study that agreed with the ones detected through Play Audiometry (cf instrumental conditioned reflex audiometry—Page 17) In children less than 2 1/2 years old he was able with P G R study to gather significant data in only 50% of examined cases, but nevertheless *upheld the validity of* the method for this group too in view of the *frequent impossibility of getting children of*

such tender age to understand the mechanism of play audiometry

Conversely Borel-Maisonny observed differences at times more than 40–50 dB for the various frequencies in children aged between 3 and 6

Pellegrini revealed threshold differences of over 30 dB in children under 3 years of age, while these fluctuated between 5 and 20 dB in adults.

Pesavento on the basis of a case-list of 56 children with ages varying from 2 to 5 years, was able to establish the following:

(a) P.G.R. study achieves threshold values generally corresponding with considerable approximation to those obtained by using the Peep-show (cf instrumental conditioned reflexes—Page 17)

(b) In children aged between 3 and 5 the threshold values found by P.G.R. study can be about 10 dB above the real

(c) In children between and 3 years of age audiometry by way of P.G.R. study is sometimes the only practicable investigation method, even though it often gives threshold values higher than the real—the error may be as much as 20–25 dB above real threshold.

Sortini studied 250 preschool age children and reported having satisfactorily assessed the hearing in all cases through P.G.R. examination He was able to discuss the possibility of phonetic training in 174 cases on the basis of the data so obtained.

Germana sought the hearing threshold for 6 frequencies (250 500, 1 000, 2 000 3 000 and 4 000 c s) in 20 children aged between 6 and 13 attending a School for the Deaf in order to highlight any residue exploitable for speech-auditory training. He made a comparative study of the audiometric curves drawn from subjective tone audiometry and P.G.R. study In the latter the threshold was higher in every case the difference in curves obtained by the two methods varied from 5 to 25 dB and was always more sensitive in younger subjects especially in the acute-frequency range

Burk, who investigated 20 adults, found no significant difference between threshold values obtained through P.G.R. study and by tone audiometry

Dupon-Tersen affirmed the importance of audiometry through P.G.R. study in the case of 2 and 3-year-old children He pointed out, however that this method can give rise to errors in these subjects, since a threshold 30–40 dB higher than the real is always obtained Consequently judgment as to the possibilities of training them cannot be based solely upon data drawn from this examination

Luscher & Kusen researched on three groups of subjects whose ages ranged from 6 to 60, and detected very slight differences between threshold values obtained through P.G.R. study and from using the peep-show or classical tone audiometry The threshold by the former method was in fact always higher than the real. Grisanti (1958) studied the ratio between hearing threshold obtained through simple, i.e unconditioned, P.G.R. study and by subjective tone audiometry He detected an average difference fluctuating between 20 and 45 dB But this deviation would be appreciably increased in correspondence with the acute frequencies Grisanti related this phenomenon to the lower emotive capacity of these frequencies

Baron & Dejour subjected to control by classical tone audiometry 25 children previously examined by P.G.R. over a period of 10 years. They reported that in the majority of children—aged between 1 $\frac{1}{2}$ and 4 at the time of first examination—the control substantially confirmed with a threshold difference varying from 10 to 15 dB the audiometric curves defined

the examination is prolonged and it is hardly possible to define the subject s audiogram under such conditions Bordley et al then thought of conditioning P G.R. on the principles substantiated by Pavlov s observations More specifically they proceeded as follows routing an auditory stimulus of surely supraliminal intensity and after a few seconds, a slightly painful electric shock. The latter brought about the onset of obvious P G.R. These stimulations were repeated a certain number of times It was observed at a given moment that the sound stimulus caused P G R. to make its appearance even though it was not followed by the pain stimulus At this moment the patient could be regarded as conditioned any sound stimulus, even of intensity slightly above threshold, could bring about the appearance of P G R.

(b) Determining the hearing threshold through study of psychogalvanic reflex

The Bordley Hardy & Richter experiments were later taken up by numerous Authors who used conditioned P G R in studying the hearing capacity under different clinical and experimental conditions, and in particular for determining the hearing threshold in children. These researches could be conducted by using appropriately designed devices (psychogalvanometers) These afford a graphic recording where in the stimuli routed to the subject and changes in his skin resistance due to the psychogalvanic reflex are given.

Bordley Hardy & Richter as well as Authors who later dealt with the subject first attempted to establish whether the hearing threshold determined through P G R study tallied approximately enough with the one detected by classical tone audiometry

It is to be noted in this regard that the results of researches conducted by these Authors on adults or school-age children are fairly in agreement, and demonstrate that objective audiometry based on P G R. study achieves sufficiently reliable data on the hearing threshold.

Bordley & Hardy studied 700 subjects in this connection They achieved positive results in 95 % of examined cases More specifically they observed an average difference between the hearing threshold by classical tone audiometry and the one obtained through P G.R. study of 2 46 dB in adults and 3 60 dB in children aged between 4 and 14

Maspétiol Gourgerot & Korine revealed that the threshold obtained through P G.R. study was higher (and thus the hearing loss more severe) than that drawn from conventional tone audiometry by 10–20 dB in adults and children over 8 years of age. This difference rose to 15–25 dB in subjects aged between 4 and 8, to 20–30 dB in 3–4 year-olds and 30–40 dB in 2–3 year-olds These Authors also pointed out the frequency of failures in subjects under 3 years of age

Conversely Faure, Portmann, Dutertre & Bramerle observed that the threshold differences in adults were contained to within 2 and 3 dB, but they rose to 10 dB in subjects aged between 4 and 7 to 15–20 dB in 2 1/2- to 4-year-olds and to 20–30 dB in those under 2 1/2

According to Pagano who studied children aged between 4 and 7 the difference between the threshold obtained by examinations via P G R. study and the one detected by classical tone audiometry does not exceed 10–15 dB

Doeffler & McClure examined 30 adult subjects and detected an average difference of 3.50 dB between the threshold by traditional tone audiometry and the one obtained through P G R. study

Barr performed examinations on 324 children aged between 1 and 6 In subjects over 2 1/2 years of age he obtained in 85 % of cases threshold values with P G.R study that agreed with the ones detected through Play Audiometry (cf instrumental conditioned reflex audiometry—Page 17) In children less than 2 1/2 years old he was able with P G R. study to gather significant data in only 50 % of examined cases, but nevertheless upheld the validity of the method for this group too in view of the frequent impossibility of getting children of

especially if the examination is repeated after an interval of some days and its practical value is controlled at a distance of 5 to 6 years. Indeed, they hold that P G R study is the only method that allows immediate fitting of a hearing aid and adequate training.

Bedoni examined through P G.R. 10 subjects affected by a more-or-less high degree of post traumatic perceptive deafness, in order to seek what he calls the Soglia di Incomoda Audibilità (S.I.A. = Uncomfortable Audibility Threshold) i.e. the lowest sound intensity capable of bringing about the onset of P G.R. According to Bedoni, this investigation procedure has given positive results also for medicolegal purposes it would be capable of providing useful elements for localizing the auricular lesions responsible for post-traumatic hearing deficiencies.

Grisanti (1967) carefully investigated by spontaneous—i.e. unconditioned—P.G.R. 128 children under 10 years of age, and 72 adult patients. He reports that it was possible to complete the examination in the child group, obtaining enough indication as to subjects auditory conditions in the majority of cases (81.5) But the examination was not crowned with success in the remaining 18.5 owing either to absence of a psychogalvanic reaction (9.8) or to the small patient's behaviour (8.7).

Bearing in mind the patients ages, Grisanti maintains that failures generally occur in very small children for the following reasons.

1 Within the first and second year of life psychogalvanic reactivity may be lacking or be very slight due either to a lower activity of the sympathetic system, or to high skin impedance

In 4- and 5-year-old children, spontaneous R G R study (without recourse to faradic shock) can also give rise to reactions, and to agitation and crying in particular

In the adult group simulated deafness was successfully ascertained in 52.3 % of cases, psychogenic deafness in 10.8 and real deafness in 35.3 %.

Grisanti therefore maintains that audiometry based on P.G.R. study besides being the only practical method of assessing hearing in children under 4 years of age, is a valid aid to diagnosing simulated or non-organic deafness.

In a later research (1968) Grisanti subjected a group of 18 normal-hearing individuals of different ages to voice audiometric investigations through P G.R. study Complete-sense disyllables were routed into the earphones and intercalated by the word "scossa" (shock) which was combined with a faradic shock.

The combination was repeated until a constant psychogalvanic reflex was obtained. Once conditioning was established the intensity of the phonemes was reduced until the words proved no longer to be intelligible though still heard by the patient: clearly the psychogalvanic reflex did not come about in such conditions.

Grisanti maintains that the procedure he used may prove very useful in studying auditory lesions of central origin and in simulators who complain of more marked deafness for speech than for pure tones.

Piragine & Bazzana found that when performing audiometry through P G.R. study difficulties may be encountered in relation to the variations presented by sweating in the different subjects under examination. They therefore studied the changes brought about in this reflex by two parasympathotropic drugs: pilocarpine which, as is known, induces sweat, and atropine which inhibits it. The investigation was conducted on 9 subjects chosen for their ready conditionability and on 4 patients who were hard to condition. On the basis of their results the Authors report that pilocarpine promotes the onset and increases the amplitude of the responses in relation to P G R., while atropine produces an opposite effect. These data can be utilized in current practice: it is in fact to be borne in mind among other things that some particularly expert simulators might make use of atropine to mask the results of audiometric tests based on P.G.R. study

Despite the lively interest aroused in many researchers by objective audiometry based on

4–5 years earlier through P G R study They thus maintain the usefulness of this investigation method for diagnosing deafness in children where subjective" audiometry is impracticable *owing to their age. Baron & Dejour also* affirm the need to compare the results from *P G R. study with those obtained by free field* voice audiometry and if possible supplement *them by other medico-educational and E.E.G* examinations, especially when disturbances of *the central nervous system are suspected.*

Fedele recently studied 32 children aged between *2 and 8* and whose mental age was noticeably lower A group of 16 with ages ranging from 2 to 5 were examined through P G R. and peep-show Fedele reports having on the whole achieved satisfactory results in these cases with both investigation methods He further affirms that a comparative study of data drawn from the two methods demonstrates audio-psychogalvanometry often to be a useful complement to investigation with the peep-show even though the threshold by P G R is usually somewhat higher generally over 10–15 dB in fact.

To conclude, therefore the investigations by different Authors into the possibilities of conditioned P G R. in audiometry do not always furnish perfectly consistent data

The researchers who examined adults usually maintain that the hearing threshold obtained through P G R study tallies substantially with the one by classical tone audiometry (Bordley & Hardy 1949 Faure Portmann Dutertre & Bramerie, 1952 Doerfler & McClure 1954 Burk 1958) Nevertheless, in these subjects too some Authors observed differences flutuating between 5 and 20 dB in the thresholds defined by the two methods (Maspétiol Cougerot & Korine 1951 Pellegrini, 1955) These differences are generally very much more noticeable in children and become more marked as the age lowers. According *to some (e g., Pesavento, 1957)* the threshold differences for children under *3 vary from* 20 to 25 dB and to others (Maspétiol Gougerot & Korine, 1951 *Dupon-Tersen 1958) from* 30 to 40 dB

(c) Possibilities of using psychogalvanic reflex in infant audiometry

The usefulness of audiometric investigations based on P G R. study has been maintained by several researchers, not only because this method enables the hearing threshold to be defined even without the patient s active co-operation but because it reveals simulated deafness and sometimes identifies within certain limits the hearing losses due to lesion of the central nervous system

Faure Portmann & Portmann examined subjects *affected by various types of deafness.* They reached the conclusion that the objective audiogram obtained through P G R study enables the extent of hearing deficiency due to lesions of the peripheral structures of the hearing organ to be established with sufficient accuracy Much more complicated however is interpretation of the data found by this method in cases of hearing loss through lesion of the nerve centres wherein according to these Authors it is often useful also to perform an E.E.G examination

Manfredi (1952) affirmed the importance of P G R. study in audiometry He later (1954 1956) brought modifications to the classical method conditioning the subject with a stimulus induced by a voltaic rather than galvanic current (psychovoltaic reflex) He reports having been able by this method to perform the examination on patients from whom due to the small amplitude of reflexes, it had not been possible to achieve reliable results by the ordinary process.

Goldstein (1956) studied 20 subjects displaying psychogenic deafness. In 10 cases he *failed to achieve conditioning,* while in the other 10 unreliable graphs were recorded although the *conditioning* was obtained Goldstein thus considered it advisable to perform an electroencephalogram in addition to the P G R study in these cases

Baron Roul & Thalamot affirm that investigations through P G R study are a valid aid to early diagnosis *of deafness in children,*

Initially studied were 24 subjects 6 to 8 years old, taken at random in a school for mentally handicapped children. This group had however to be re-set up because the percentage of failures was too high. The Authors therefore asked teachers to point out the individuals most likely to co-operate. Thus 34 subjects whose average I.Q. was 0.37 were selected. In only 24 of these cases, however could reliable recordings be obtained.

We think it important in this connection to draw attention to a datum given by these Authors: of the 24 children for which a full recording was made, 13 were mongoloid, and hence very tranquil subjects. In the 10 children where an audiogram could not be obtained, the causes of failure were: negativism, hyperactivity shyness total rejection and, in one case, even a violent cough at the start of the test.

With regard specifically to the examinations performed by conditioning the patients with a light stimulus it is to be pointed out that some had fear reactions while others even went to sleep during the test.

On the whole the Authors concluded that only in a small percentage of mentally deficient children can reliable P.G.R. recordings be secured. They therefore questioned, in accord with Irwin, Hind & Aronson, whether audiometric research by such a painstaking method a psychogalvanic examination is justified when there are other techniques easier to perform. They pointed out in this connection that it is difficult to execute a reliable audiogram by P.G.R. study for a subject with mental handicaps who is incapable of co-operating in the investigation conducted by ordinary infant audiometry techniques.

More recently a careful analysis of the possibilities of P.G.R. study within the infant-audiometry field was done by Préfot & Lafon, who found that failures can occur with normal-hearing children by this technique either due to high skin impedance or to impossibility of provoking an emotive shock in the child owing to its age or lastly to the impossibility of achieving conditioning even after repeated tests.

Préfot & Lafon also noted that in the course of P.G.R. study into severely deaf children, interferences related to accidental stimuli overlapping the sound stimulus can be recorded in the tracings and these of course affect the results of the examination. They therefore conclude that audiometry through P.G.R. study has not fulfilled the hopes raised by the first experiments of Bordley and colleagues. In current practice this technique is delicate and offers numerous possibilities of error especially in the case of subjects of tender age. It tends for these reasons to be abandoned as an investigation method for assessing the hearing capacity of preschool age children.

2. PERSONAL RESEARCHES

(a) Investigation method

For the study of P.G.R. we adhered to the examination procedure adopted consistently by the majority of Authors who have dealt with the subject. More specifically we used a Portmann-Racia psychogalvanometer (*Fig. 1 A*) and a Grason-Stadler psychogalvanometer (Fig. 1 *B*) both equipped with two pens, one tracing the tone and possibly pain-stimulation routed to the subject, and the other the changes in skin resistance.

The examinations were performed in a perfectly silent cabin. The child was put on his mother's or the assistant's knee and was kept amused by different toys or illustrated books (*Figs. 1 A, 1 B* and *2*).

We applied two electrodes to the sole of his foot, to detect the variations in skin resistance and the ones transmitting the faradic stimulation to the opposite calf (Fig. 2). After calibrating the device the examination was started.

The examination was initially conducted on each subject in "free field" i.e., routing the sounds to a speaker located at a suitable distance from him. Later when satisfactory conditioning was established, the hearing threshold of both ears was analysed, routing the sound stimulus into the relative earphones.

P G R. study it has not always given satisfactory results in practice and has therefore been the object of criticism, especially with regard to its use in children who are very small or of low I Q., or at any rate with lesions of the central nervous system

Goldstein Polito-Castro & Daniels studied 32 normal hearing children aged between 7 and 13 They report 14 of them to have been scarcely conditionable by P G R

Statten & Wishart examined 122 children between 1 ¹/₂ and 6 years old Only in 15% of these cases did they succeed in plotting a *satisfactory audiogram. In 70% the tracing* obtained was only indicative According to these Authors *the possibilities of using the method* are limited, either because conditioning of the subjects under examination *is not established* and the skin resistance changes are slight in response to the auditory stimuli, or because there are psychological reactions on the part of the small patients that prevent completing the investigation

On the other hand since the majority of children can be examined by procedures more agreeable to them (conditioned instrumental or orientation reflex audiometry) according to these Authors, P G R. should be attempted only in cases where such types of investigation are impracticable owing, for example to severe motor deficiencies in the limbs or cephalic trunk, or to specific psychological reactions.

Celis-Perez subjected to audiometric investigation with P G R. study 25 children in early infancy 112 at pre-school age and 10 adults He found it impossible to achieve conditioning in some cases and in others there was not even response to the faradic stimulus On the other hand he also noted that a sedative premedication used in certain subjects to lessen their distress, generally causes a delay in the onset of reflexes With this in mind Celis-Perez holds that the results obtained with P G R. study are only reliable when *at least two equal audiograms* have been had in the course of tests carried *out at a distance* of some days between each

Slanger & Gottsleben, *after* conducting a set of experiments through P G.R. study on low I Q mentally handicapped *subjects, maintained* that this technique does not often allow reliable results to be obtained in such patients

Irwin, Hind & Aronson who investigated 20 mentally handicapped subjects aged between 9 and 38 with an average I Q of 0.50 found audiometry based on P G R study to give less satisfactory results than does conventional audiometry About one quarter of their case-list could not be examined by P G R., either because of their particular reactions or due to *difficulty in establishing conditioning.*

Schultz, starting from the assumption that *failures* in audiometry based on P G R. are often due to the fact that faradic shock provokes *a painful or at any rate unpleasant sensation* in small patients, replaced this stimulus with a luminous one (a Nitra 500 Watt photolamp) producing a sudden flash in a dark room The conditioned reflex was obtained by repeatedly combining the sound stimulus with the luminous More specifically Schultz first routed the pure tone and, after two or three seconds, the light stimulus which lasted about one second. By this method he studied 29 hearing-defective children aged between 1 and 7 and reports the examination to have been unsuccessful in 4 children, while the hearing capacity of one ear could be *determined in 16 and of both* ears in 9

Copelmann basing on results of a series of researches conducted via P G R discusses the importance of emotional factors in the nervous mechanisms that govern auditory perception

Kodman, Fein & Mixon obtained useful information in 28 of the 31 mentally handicapped children they examined by way of P G R

Moss Moss & Tizard carried out careful investigations to establish the results that are obtainable through *P G R. study in mentally* handicapped children. The patients were generally *subjected to* two tests one using electric shock as a conditioning stimulus, and the other an intense light (as Schultz had previously propounded)

Initially studied were 24 subjects 6 to 8 years old, taken at random in a school for mentally handicapped children. This group had however to be re-set up because the percentage of failures was too high. The Authors therefore asked teachers to point out the individuals most likely to co-operate. Thus 34 subjects whose average I.Q. was 0.37 were selected. In only 24 of these cases, however, could reliable recordings be obtained.

We think it important in this connection to draw attention to a datum given by these Authors: of the 24 children for which a full recording was made, 13 were mongoloid, and hence very tranquil subjects. In the 10 children where an audiogram could not be obtained, the causes of failure were: negativism, hyperactivity, shyness, total rejection and, in one case, even a violent cough at the start of the test.

With regard specifically to the examinations performed by conditioning the patients with a light stimulus, it is to be pointed out that some had fear reactions while others even went to sleep during the test.

On the whole, the Authors concluded that only in a small percentage of mentally deficient children can reliable P.G.R. recordings be secured. They therefore questioned, in accord with Irwin, Hind & Aronson, whether audiometric research by such a painstaking method as psychogalvanic examination is justified when there are other techniques easier to perform. They pointed out in this connection that it is difficult to execute a reliable audiogram by P.G.R. study for a subject with mental handicaps who is incapable of co-operating in the investigation conducted by ordinary infant audiometry techniques.

More recently a careful analysis of the possibilities of P.G.R. study within the infant-audiometry field was done by Prélot & Lafon, who found that failures can occur with normal-hearing children by this technique, either due to high skin impedance or to impossibility of provoking an emotive shock in the child owing to its age or lastly to the impossibility of achieving conditioning even after repeated tests.

Prélot & Lafon also noted that in the course of P.G.R. study into severely deaf children, interferences related to accidental stimuli overlapping the sound stimulus can be recorded in the tracings and these of course affect the results of the examination. They therefore conclude that audiometry through P.G.R. study has not fulfilled the hopes raised by the first experiments of Bordley and colleagues. In current practice this technique is delicate and offers numerous possibilities of error especially in the case of subjects of tender age. It tends for these reasons to be abandoned as an investigation method for assessing the hearing capacity of preschool-age children.

2. PERSONAL RESEARCHES

(*a*) Investigation method

For the study of P.G.R. we adhered to the examination procedure adopted consistently by the majority of Authors who have dealt with the subject. More specifically, we used a Portmann-Racia psychogalvanometer (Fig. 1 *A*) and a Grason-Stadler psychogalvanometer (Fig. 1 *B*), both equipped with two pens, one tracing the tone and possibly pain-stimulation routed to the subject, and the other the changes in skin resistance.

The examinations were performed in a perfectly silent cabin. The child was put on his mother's or the assistant's knee, and was kept amused by different toys or illustrated books (Figs. 1 *A*, 1 *B* and 2).

We applied two electrodes to the sole of his foot, to detect the variations in skin resistance, and the ones transmitting the faradic stimulation to the opposite calf (Fig. 2). After calibrating the device the examination was started.

The examination was initially conducted on each subject in "free field", i.e., routing the sounds to a speaker located at a suitable distance from him. Later, when satisfactory conditioning was established, the hearing threshold of both ears was analysed, routing the sound stimulus into the relative earphones.

P G R. study it has not always given satisfactory results in practice and has therefore been the object of criticism especially with regard to its use in children who are very small or of low I Q., or at any rate with lesions of the central nervous system

2. PERSONAL RESEARCHES

(a) Investigation method

For the study of P.G.R. we adhered to the examination procedure adopted consistently by the majority of Authors who have dealt with the subject. More specifically we used a Portmann-Racm psychogalvanometer (*Fig. 1 A*) and a Grason-Stadler psychogalvanometer (Fig. 1 *B*), both equipped with two pens one tracing the tone and possibly pain-stimulation routed to the subject, and the other the changes in skin resistance.

The examinations were performed in a perfectly silent cabin. The child was put on his mother's or the assistant's knee, and was kept amused by different toys or illustrated books (Figs. 1 *A*, 1 *B* and 2).

We applied two electrodes to the sole of his foot, to detect the variations in skin resistance, and the ones transmitting the faradic stimulation to the opposite calf (Fig. 2). After calibrating the device the examination was started.

The examination was initially conducted on each subject in "free field", i.e., routing the sounds to a speaker located at a suitable distance from him. Later when satisfactory conditioning was established, the hearing threshold of both ears was analysed, routing the sound stimulus into the relative earphones.

P G R study it has not always given satisfactory results in practice and has therefore been the object of criticism especially with regard to its use in children who are very small or of low I Q or at any rate with lesions of the central nervous system

Goldstein Polito-Castro & Daniels studied 32 normal-hearing children aged between 7 and 13 They report 14 of them to have been scarcely conditionable by P G R

Statten & Wishart examined 122 children between 1 $^1/_2$ and 6 years old Only in 15% of these cases did they succeed in plotting a satisfactory audiogram In 70% the tracing obtained was only indicative According to these Authors, the possibilities of using the method are limited either because conditioning of the subjects under examination is not established and the skin resistance changes are slight in response to the auditory stimuli or because there are psychological reactions on the part of the small patients that prevent completing the investigation

On the other hand, since the majority of children can be examined by procedures more agreeable to them (conditioned instrumental or orientation reflex audiometry) according to these Authors P G.R should be attempted only in cases where such types of investigation are impracticable owing, for example, to severe motor deficiencies in the limbs or cephalic trunk or to specific psychological reactions

Celis-Perez subjected to audiometric investigation with P G R. study 25 children in early infancy 112 at pre school age, and 10 adults. He found it impossible to achieve conditioning in some cases, and in others there was not even response to the faradic stimulus On the other hand he also noted that a sedative premedication used in certain subjects to lessen their distress, generally causes a delay in the onset of reflexes With this in mind Celis-Perez holds that the results obtained with P G R study are only reliable when at least two equal audiograms have been had in the course of tests carried out at a distance of some days between each

Slanger & Gottsleben after conducting a set of experiments through P G.R. study on low I Q mentally handicapped subjects, maintained that this technique does not often allow reliable results to be obtained in such patients.

Irwin Hind & Aronson, who investigated 20 mentally handicapped subjects aged between 9 and 38 with an average I Q of 0.50 found audiometry based on P G R. study to give less satisfactory results than does conventional audiometry About one quarter of their case-list could not be examined by P G R., either because of their particular reactions or due to difficulty in establishing conditioning.

Schultz, starting from the assumption that failures in audiometry based on P G R are often due to the fact that faradic shock provokes a painful or at any rate unpleasant sensation in small patients replaced this stimulus with a luminous one (a Nitra 500 Watt photolamp) producing a sudden flash in a dark room. The conditioned reflex was obtained by repeatedly combining the sound stimulus with the luminous More specifically Schultz first routed the pure tone and after two or three seconds, the light stimulus which lasted about one second By this method he studied 29 hearing defective children aged between 1 and 7 and reports the examination to have been unsuccessful in 4 children while the hearing capacity of one ear could be determined in 16 and of both ears in 9

Kodman Fein & Mixon obtained useful information in 28 of the 31 mentally handicapped children they examined by way of P G R

Moss, Moss & Tizard carried out careful investigations to establish the results that are obtainable through P G R study in mentally handicapped children The patients were generally subjected to two tests one using electric shock as a conditioning stimulus, and the other an intense light (as Schultz had previously propounded)

Fig. 2. Audiometric examination by P.G.R. study. On her mother's lap the child is entertained with a story-book. Note the electrode arrangement.

The chief causes of failure were agitation and subsequent crying, which often followed upon the first faradic shock.

(b) Results

Our data on the 35 patients we examined are given in Table 1.

The results obtained in the different cases were classified into three groups, i.e.

Negative: when there was no precise indication as to the patient's hearing capacity.

Indicative: when it was managed to establish whether the subject was normal-hearing, hard-of-hearing or severely deaf, but without being able to define the hearing threshold for the various examined frequencies.

Positive: when the thresholds for the explored tones could be ascertained especially for 250, 500, 1 000, 2 000 and 4 000 c/s which, as we know, are the frequencies included within conversational voice.

Taking overall the data in Table 1 relative to the 35 patients, it is to be seen that: for 13 (37 %) the examination did not enable useful data to be found; for 18, i.e. about 51 %, only indicative data were derived; for 4 or 11 % only sufficiently accurate threshold values could be achieved.

Table 1. *Results obtained for 35 patients examined through P.G.R. study*

Age (years)	No. cases	Results: Negative		Indicative		Positive	
1–2	8	5	62.5	3	37.5	—	
3	13	4	30.8	7	53.8		15.4
3–4	14	4	28.6	8	57.1	2	14.3
Total	35	13	37.1	18	51.4	4	11.5

A more detailed analysis of these data also reveals that:

1. The failure percentage was very high in subjects under 2 years of age (62 % negative results): only in a somewhat modest proportion (37 %) was it possible to have indicative data.

2. In patients over 2 the percentage of negative results progressively lowered while the number of cases wherein indicative data were obtained increased (about 54 %) but the proportion for which really useful data were obtained (positive results) was always extremely low, i.e., around 15 %.

(c) Considerations

As we have mentioned, the opinions of different researchers into the validity of psychogalvanometry and especially into the expediency of using this technique in consulting-room practice for audiometric investigation into pre-school-age or low I.Q. subjects, are rather discordant.

In our view, audiometric examination based on P.G.R. study presents three basic aspects: one positive and two highly negative.

The positive element in this investigation method, on the theoretical and practical plane, is chiefly pavlovian conditioning, which rules out any active participation in the examination by the small patient.

Fig 1(A–B). (*A*) A 4 year old examined audiometrically by P G.R. study (Portmann-Racia Psychogalvanometer). Letting him have toys helps to establish contact, attenuate his reactions to the painful stimulus and get him interested in the examination. (*B*) Audiometric examination of a 3 year-old by P G R. study (Grason-Stadler Psychogalvanometer marketed by Amplifon)

We began the investigation by routing into the earphone a deep-frequency sound (250 or 500 c/s) whose intensity was definitely supraliminal The task of this stimulus was to test the subject's reactivity The patient was then conditioned by combining the sound stimulus with faradic stimulation, at an interval of a few seconds When conditioning was achieved we routed the sound stimulus only progressively reducing its intensity 10 dB at a time, in order to establish the threshold which tallied with minimum intensity of the stimulus capable of bringing about a skin reaction At intervals, when the psychogalvanic reflex tended to expire it was revived by making a faradic stimulus precede the sound one. The various frequencies were tested by this technique until a complete audiometric curve was found.

To check reliability of the data obtained, the results of the P G R examination were always verified by other types of objective audiometry i.e instrumental conditioned reflex (I C.R.) or conditioned orientation reflex (C.O R.) study

Fig. 2. Audiometric examination by P.G.R. study. On her mother' lap, the child is entertained with a story book. Note the electrode arrangement.

The chief causes of failure were agitation and subsequent crying, which often followed upon the first faradic shock.

(*b*) Results

Our data on the 35 patients we examined are given in Table 1.

The results obtained in the different cases were classified into three groups, i.e.

Negative when there was no precise indication as to the patient's hearing capacity.

Indicative when it was managed to establish whether the subject was normal-hearing, hard-of-hearing or severely deaf, but withoun being able to define the hearing threshold for the various examined frequencies.

Positive when the thresholds for the explored tones could be ascertained especially for 250 500 1 000 2 000 and 4 000 c.s which, as we know are the frequencies included within conversational voice.

Taking overall the data in Table 1 relative to the 35 patients, it is to be seen that for 13 *i.e.* 37 the examination did not enable useful data to be found for 18, *i.e.* about

Table 1. *Results obtained for 35 patients examined through P.G.R. study*

Age (years)	No. cases	Results					
		Negative		Indicative		Positive	
		n	%	n	%	n	%
1 2	8	5	62.5	3	37.5	—	
2 3	13	4	30.8	7	53.8	2	15.4
3–4	14	4	28.6	8	57.1	2	14.3
Total	35	13	37.1	18	51.4	4	11.3

51% only indicative data were derived for 4 or 11% only sufficiently accurate threshold values could be achieved.

A more detailed analysis of these data also reveals that.

1. The failure percentage was very high in subjects under 2 years of age (62% negative results) only in a somewhat modest proportion (37%) was it possible to have indicative data.

2. In patients over 2 the percentage of negative results progressively lowered while the number of cases wherein indicative data were obtained increased (about 54%) but the proportion for which really useful data were obtained (positive results) was always extremely low i.e. around 15%.

(*c*) Considerations

As we have mentioned, the opinions of different researchers into the validity of psychogalvanometry and especially into the expediency of using this technique in consulting-room practice for audiometric investigation into pre school-age or low I.Q. subjects, are rather discordant.

In our view audiometric examination based on P.G.R. study presents three basic aspects one positive and two highly negative.

The positive element in this investigation method, on the theoretical and practical plane, is chiefly pavlovian conditioning, which rules out any active participation in the examination by the small patient.

Fig 1(A B). (c) Considerations

As we have mentioned, the opinions of different researchers into the validity of psychogalvanometry and especially into the expediency of using this technique in consulting-room practice for audiometric investigation into pre-school-age or low I.Q. subjects, are rather discordant.

In our view audiometric examination based on P.G.R. study presents three basic aspects: one positive and two highly negative.

The positive element in this investigation method, on the theoretical and practical plane, is chiefly pavlovian conditioning, which rules out any active participation in the examination by the small patient.

The two negative factors are

1 The subject s handling before the examina tion (placing electrodes in situ and calibrating the device) this certainly does not enable good contact to be made with the child

2 The conditioning stimulus which being a faradic shock is undeniably unpleasant and often provokes unfavourable reactions on the part of the small patient

These two negative factors generally cancel out the advantages of pavlovian conditioning

As indeed has been mentioned the faradic shock is not only not a "reward" to the small patient on the psychological plane, but even brings on negative reactions. In our own ex perience in fact, the child s agitation and subsequent crying, during both preparatory stage and first conditioning period were the principal causes of failure

On other occasions though first conditioning was established, the negative reactions arose as a result of subsequent, high-intensity faradic stimulations. Lastly to be numbered among the causes of failure was uncontrollable psychomotor agitation, often present in patients of tender age and especially in those with severe mental disorders—and any sedative treatment, besides not being readily practicable in the consulting room often does not give good re sults, as the researches by Facchini & Silimbani demonstrate P G R. cannot in fact be provoked in a state of somnolence.

Our data thus agree basically with those of previous Authors (Goldstein, Polito-Castro & Daniels Goldstein Slanger & Gottsleven Moss, Moss & Tizard Prélot & Lafon) who precisely pointed out the difficulties of examination based on P G R. study in children, and drew attention chiefly to the following causes of failure. opposition or total refusal to submit to the examina tion shyness, hyperactivity fear and some times also violent coughing at the start of the test.

As mentioned, some Authors (Schultz, Moss, Moss & Tizard) used an intense light rather than faradic shock in order to lessen these drawbacks but even with this procedure the results were not on the whole satisfactory

3 CONCLUSIONS

Data in the literature and the results of our own researches demonstrate that audiometric investigations by P G R. study in children often give unsatisfactory results and a particularly high percentage of failures. We consider for these reasons that P G.R study should be set aside for specific cases only and that proce dures taking into account children s motivations and interests should generally have preference in audiometric investigations

CHAPTER 2

Instrumental Conditioned Reflexes

1 PREVIOUS RESEARCHES

In 1944 Ewing & Ewing conducted investigations into 2 to 3 year-old children, using a set of toys capable of attracting their attention. These were: coloured wooden rods which were slipped into holes, also coloured, cylinders which had to be fitted into different-sized hollows variously coloured bobbins which were slipped on to pins brightly coloured rings of different diameter which had to be slipped on to a stick to make up a cone

The young patient s mother or an assistant to the examiner drew his attention to one of these games. When the child seemed interested in his chosen game, an attempt was made to condition him through sound stimuli provided by a whistle or drum, or a bell behind him. He had in fact to begin playing with the toy when these auditory stimuli were sent.

This type of investigation was called Play Audiometry

But credit unquestionably goes to Dix & Hallpike for having, in 1947 introduced into clinical practice a method of instrumental conditioning for examining deaf children, which quickly claimed the attention of specialists, both for its ease in use and chiefly because it achieves excellent results.

In their investigations Dix & Hallpike used device called peep-show This is basically a screen upon which are projected images or figures capable of gaining the attention or amusing the patient (animated cartoons, fairy-tale characters, etc). The projector is linked up to a pushbutton and an audiometer The sounds can be routed to a speaker when the audiometric examination is performed in free field, or straight to the patient's ear by an earphone when it is wanted to explore the two auditory apparata separately The circuit is regulated so that when the sound is present in the earphones or speaker it is enough to depress the pushbutton in order for the figures to appear on the screen. Conversely when there is no sound stimulus the image will not appear on the screen even though the child depresses the pushbutton.

To carry out the investigation the patient must be made to understand that in order to see the figures on the screen, he has to depress the pushbutton as soon as he hears the sound stimulus If the child is well conditioned he will not even attempt to use the pushbutton during the silent periods, whereas he will depress it with varying frequency and force when he hears the sounds. This will give the examiner proof that the stimulus has been perceived.

The audiometric thresholds can thus be established for the various frequencies, and an audiogram plotted.

According to some makers, conditioning can be facilitated by introducing a further prop this would be a weak red-violet lamp placed above the screen, which lights up only when the figures appear

The majority of Authors however disclaim the usefulness of this prop which can undoubtedly create confusion at the conditioning stage

It is to be briefly underlined that clear differences exist between instrumental conditioned reflexes (I.C.R.) and the pavlovian.

I.C.R., such as those utilized for instance

in investigations conducted with the peep-show *make use of a skeletal muscular response se curely bound up with activity of the cortical* nerve centres, and thus controlled by the will. Pavlovian conditioned reflexes, however which are exploited typically in audiometry based on P G R. study are generally visceral reactions attendant upon stimuli of the autonomic ner vous system and certainly not influenced by the patient s will

Since audiometry based on use of the peep-show exploits study of the reflexes involving active participation by the subject, it is also called semi-objective

Various Authors, persuaded of the usefulness of this type of audiometry have suggested nu merous modifications to Dix & Hallpike s orig-inal equipment in order to improve and chiefly promote responses of the small patients The basic purpose of these different techniques is to create situations that better accord with the child s *motivations More specifically different* attractive objects are placed at the young pa tient s disposal that enable him to start a game The *sound stimulus is practically one of the* elements of this game, and thus capable of arousing his interest In other words reaction to the auditory stimulus is part of the game to the child, while for the examiner it is proof that he hears the stimulus

We briefly recall here the principles of various modifications proposed for the Dix & Hallpike peep-show

1 Denmark used as a reward a roundabout with coloured horses on the stage of a toy theatre His examinations were performed both in free field and earphone

2 Guilford & Haug introduced a device which they called Pediacumeter This is a toy theatre with seven puppet heads that pop out one at a time as a result of the pressure the patient can exert upon a button

3 Portmann & Portmann (1953) used a projector with transparencies figuring characters drawn from popular fairy tales or at any rate known to the children

4 Barr used wooden fit in toys similar to those of Ewing & Ewing (cf page 17), the difference being that he made use of auditory stimuli provided by an audiometer

5 Statten & Wishart utilized an animated cartoon projected on to a screen set up on the facade of a dolls house the cine projector was inside the house

6 Schimizu & Nakamura found useful figures that were projected on to a large screen set up behind a partition of the room (lantern slide test)

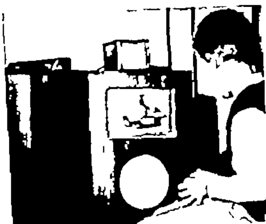
7 Green thought of using some of the bat tery-driven toys now widely available He stud-ied the pup-show in particular This is a small mechanical puppy that went through move-ments when the child depressed the button on hearing the tone

8 Herzon used a device similar to that of Schimizu & Nakamura the Photoaudio Con ditioning Machine This is basically a projector operating in a small movie auditorium

9 *Ghirlanda proposed using a kaleidoscope* visible through a small window This is set in motion when the pushbutton is depressed

These audiometric techniques are generally recommended for children aged between 2 and 5

2 PERSONAL RESEARCHES



(a) Investigation method

As mentioned, various Authors have been in terested in I C R. audiometry and have put for ward different investigation procedures. These, however do not differ substantially from one another though varying in detail During recent years in the course of our researches we have tried various methods in an attempt to establish the advantages and drawbacks of each of them in relation also to previous Authors experience

Among these methods—which essentially en-able all to achieve satisfactory results—the one put forward by *Green appears specially ad* vantageous in view of the simplicity of the de-vices it requires besides the lack of difficulty *in carrying out the investigation.*

As stated Green used a small mechanical

Figs 3 4 Audiometric examination by free-field I.C.R. study using show with projector for transparencies. This show can also be used for C.O.R. study

puppy (pup-show) for conditioning the child when the patient depresses the button, the puppy's eyes light up and it does some jumps at the same time.

This game brought about fear reactions in many children, thereby hindering continuation of the research. We therefore thought it useful to replace Green's puppy with other toys, chosen from those most interesting and familiar with a view not only to overcoming this drawback but to stimulating the child's interest more and keeping it alive.

To be borne in mind in this connection is that suspicion and fickleness are the character disturbances most frequently met with in young deaf patients. These often make first contact between examiner and patient rather difficult. Using toys that all children know undoubtedly facilitates this contact, while their variety allows the examination to be prolonged until a complete audiogram is obtained

In our investigations we preferred to use either a screen upon which animated cartoons and colour transparencies figuring characters drawn from the better-known fairy tales were projected (Figs. 3 and 4) or mechanical

in investigations conducted with the peep-show make use of a skeletal muscular response securely bound up with activity of the cortical nerve centres, and thus controlled by the will Pavlovian conditioned reflexes however which are exploited typically in audiometry based on P G R study are generally visceral reactions attendant upon stimuli of the autonomic nervous system and certainly not influenced by the patient s will

Since audiometry based on use of the peep-show exploits study of the reflexes involving active participation by the subject, it is also called semi-objective

Various Authors, persuaded of the usefulness of this type of audiometry have suggested numerous modifications to Dix & Hallpike s original equipment in order to improve and chiefly promote responses of the small patients The basic purpose of these different techniques is to create situations that better accord with the child s motivations More specifically different attractive objects are placed at the young patient s disposal that enable him to start a game The sound stimulus is practically one of the elements of this game, and thus capable of arousing his interest. In other words, reaction to the auditory stimulus is part of the game to the child, while for the examiner it is proof that he hears the stimulus

We briefly recall here the principles of various modifications proposed for the Dix & Hallpike peep-show

2 PERSONAL RESEARCHES

(*a*) Investigation method

As mentioned various Authors have been interested in I C R. audiometry and have put forward different *investigation procedures*. These, however do not differ substantially from one another though varying in detail During recent years in the course of our researches, we have tried various methods in an attempt to establish the advantages and drawbacks of each of them in relation also to previous Authors experience

Among these methods—which essentially enable all to achieve *satisfactory results*—the one put forward by Green appears specially advantageous in view of the simplicity of the devices it requires, besides the lack of difficulty in carrying out the investigation.

As stated, Green used a small mechanical

These results were classified as negative in dicative and positive by the same criteria as reported on page 15 Our data enable us to find the following:

1 The overall proportion of positive results was 76.2% This result is therefore particularly satisfactory

2. Indicative results were obtained only in a very small number of patients i.e., 8 6% of examined cases

3 The percent number of cases from which useful audiometric data were drawn rises progressively as patients' ages increase whereas failures were rather infrequent in children over 3 years of age, the percentage of negative results remained relatively high in those of lower age In subjects between 2 and 2 ½ years of age particularly this proportion reached 50% of examined cases.

(c) Considerations

As we see, numerous Authors have used I.C.R. study in audiometric investigations into children. Table 3 gives some data from the literature relative to the percentage of positive results attainable by such investigations into children of varying ages.

The results of our own researches agree essentially with those of earlier Authors, as regards both the progressive percent increase of successes in relation to rise in the age of patients and the high incidence of positive results in the groups over 3 years of age

Our observations (Table _) show too, that the percentage of indicative results obtained with I C R study is very low This is readily explained when the characteristics of the investigation method are borne in mind It is evident in fact that the child under test, either understands the relatively simple mechanisms underlying the method and correctly performs the conditioned-reflex movements, enabling the audiogram to be found, or he is not conditioned, and the examination fails

Table 3. *Results obtained by various Authors through I C.R. study*

Percentage of cases wherein positive results were achieved

Author	Age of examined patients (years)				
	5–6	4–5	3–4	2–3	1 2
Barr (1955)	92	81	71	41	
Sutton & Wishart (1956)	90	93	79	43	7
Haug & Guilford (1960)	96	94	82	47	12
Motta, Facchini & D'Auria		90	82	49	

The highest percentage of indicative results was had in the group of very young children whose restlessness, fatigue or other failure factors already taken into account by us for P G.R., lessened the probabilities of success in the test.

We must point out, finally the impossibility of conducting investigations by the above method into children who have severe visual defects We found this to be the case with two children in whom severe auditory damage was combined with a congenital cataract. Both pathological processes had arisen through measles suffered by the mother during the first months of pregnancy Investigation through P G.R. study enabled the hearing threshold to be established with considerable accuracy in these two cases.

3 CONCLUSIONS

Audiometric investigations based on I.C.R. study afford remarkably satisfactory results in children, especially when they are implemented with appropriate skills. The percentage of satisfactory indicative or positive results is noticeably high—around 86%—in children over 3 years old. In lower-aged patients this proportion lowers progressively and drops even to 31% in the group under 2 ½ years of age. It is therefore expedient that more suitable techniques be employed for these patients.

Fig 9 To train the child to react with the right movements to auditory stimuli, his mother or a social assistant can teach him to arrange skittles in a given order at each drum beat.

It is advisable for the child to keep his hand a little away from the pushbutton so as to prevent him from making too wide and complicated movements This is especially to be borne in mind with smaller children

Once conditioning is achieved the threshold for the various frequencies is to be sought by reducing the stimulating sound intensity by 10 dB at a time

When it is found that a frequency is not heard even at maximum intensity provided by the audiometer it is advisable also to test the neighbouring frequencies, since there may be islands" in correspondence with these wherein the sound stimulus is heard.

Sometimes a satisfactory conditioning of the child cannot be achieved during the first session In such event it is preferable rather than tire or irritate him to suspend the examination and repeat it later—even after only a few hours If despite this precaution the examination cannot be completed, it will be expedient before persisting further in the tests to instruct the parents in showing the child how to handle different educational toys (blocks fit in cylinders, etc) after an intense sound stimulation

As an instance the child s mother will be advised to have him arrange skittles in a certain order He will place one skittle at a time as soon as mother gives one beat to a drum (Fig. 9) The drum will first be held in front of the child so that he associated the visual with the auditory stimulus. Then the visual stimulus must be removed, the drum being placed behind the child and the auditory stimulus sent, taking care that he does not see his mother s hand movement as she beats the drum

As mentioned, these exercises, which can be done without difficulty with the help of parents, undoubtedly make later audiometric examinations easier since they already establish the child s conditioning to auditory stimuli.

It is preferable at the beginning to perform the examination in free field since better cooperation by the child is achieved in these conditions. To be pointed out in this regard is that children often refuse to put on the earphone and may if opposed, react, making any conditioning a painstaking business.

The investigation can in any case be completed another time repeating the examination in earphones when the child has learnt to cooperate with the examiner

(*b*) Results

With the equipment and by the techniques described we examined 151 subjects aged between 2 and 5 Our results are given in Table 2

Table 2. *Results obtained from 151 patients examined by way of I C R study*

Age (years)	No cases	Results: Negative n	%	Indicative n	%	Positive n	%
2½	16	8	50.0	3	18.7	5	31.3
2½–3	23	6	26.1	3	13.0	14	60.9
3–4	60	7	11.6	4	6.7	49	81.7
4–5	52	2	3.8	3	5.8	47	90.4
Total	151	23	15	13	8.6	115	76.2

These results were classified as negative indicative and positive by the same criteria as reported on page 15 Our data enable us to find the following:

1 The overall proportion of positive results was 76.2%. This result is therefore particularly satisfactory

2. Indicative results were obtained only in a very small number of patients, i.e., 8 6% of examined cases

3 The percent number of cases from which useful audiometric data were drawn rises progressively as patients ages increase whereas failures were rather infrequent in children over 3 years of age the percentage of negative results remained relatively high in those of lower age In subjects between 2 and 2 1/2 years of age particularly this proportion reached 50% of examined cases.

(c) Considerations

As we see numerous Authors have used I.C.R. study in audiometric investigations into children Table 3 gives some data from the literature relative to the percentage of positive results attainable by such investigations into children of varying ages.

The results of our own researches agree essentially with those of earlier Authors, as regards both the progressive percent increase of successes in relation to rise in the age of patients and the high incidence of positive results in the groups over 3 years of age

Our observations (Table 2) show too, that the percentage of indicative results obtained with I C R. study is very low This is readily explained when the characteristics of the investigation method are borne in mind. It is evident in fact that the child under test, *either* understands the relatively simple mechanisms underlying the method and *correctly* performs the conditioned-reflex movements, enabling the audiogram to be found, or he *is not conditioned*, and the examination fails.

Table 3 *Results obtained by various Authors through I C.R. study*

Percentage of cases wherein positive results were achieved

Author	Age of examined patients (years)				
	5–6	4–5	3–4	2 3	1 2
Barr (1955)	92	81	71	41	
Statten & Wishart (1956)	90	93	79	43	7
Haug & Guilford (1960)	96	94	82	47	12
Motta, Facchini & D'Aurea		90	82	49	

The highest percentage of indicative results was had in the group of very young children whose restlessness, fatigue or other failure factors already taken into account by us for P G.R., lessened the probabilities of success in the test.

We must point out, finally the impossibility of conducting investigations by the above method into children who have severe visual defects. *We found this to* be the case with two children in whom severe auditory damage was combined with a congenital cataract. Both pathological processes had arisen through measles suffered by the mother during the first months of pregnancy Investigation through P G.R. study enabled the hearing threshold to be established with considerable accuracy in these two cases.

3 CONCLUSIONS

Audiometric investigations based on I.C.R. *study afford* remarkably satisfactory results in children, especially when they are implemented with appropriate skills. The percentage of satisfactory indicative or positive results is noticeably high—around 86%—in children over 3 years old. In lower-aged patients this proportion lowers progressively and drops even to 31% in the group under 2 1/2 years of age. It is therefore expedient that more suitable techniques be employed for these patients.

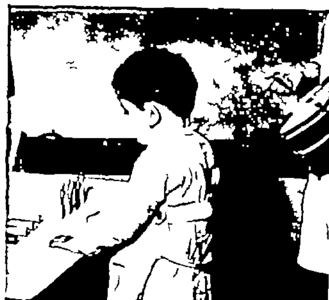

Fig 9 To train the child to react with the right move ments to auditory stimuli his mother or a social assistant can teach him to arrange skittles in a given order at each drum beat.

It is advisable for the child to keep his hand a little away from the pushbutton, so as to prevent him from making too wide and com plicated movements This is especially to be borne in mind with smaller children

Once conditioning is achieved the threshold for the various frequencies is to be sought by reducing the stimulating sound intensity by 10 dB at a time

When it is found that a frequency is not heard even at maximum intensity provided by the audiometer it is advisable also to test the neighbouring frequencies, since there may be islands" in correspondence with these wherein the sound stimulus is heard

Sometimes a satisfactory conditioning of the child cannot be achieved during the first ses sion In such event it is preferable, rather than tire or irritate him to suspend the examination and repeat it later—even after only a few hours. If despite this precaution, the examina tion cannot be completed it will be expedient before persisting further in the tests to instruct the parents in showing the child how to handle different educational toys (blocks, fit-in cylinders etc) after an intense sound stimulation.

As an instance, the child s mother will be advised to have him arrange skittles in a certain order He will place one skittle at a time as soon as mother gives one beat to a drum (Fig. 9) The drum will first be held in front of the child so that he associated the visual with the auditory stimulus Then the visual stimulus must be removed the drum being placed behind the child and the auditory stimulus sent, taking care that he does not see his mother s hand movement as she beats the drum

As mentioned these exercises which can be done without difficulty with the help of parents, undoubtedly make later audiometric examinations easier since they already establish the child s conditioning to auditory stimuli.

It is preferable at the beginning to perform the examination in free field since better co-operation by the child is achieved in these conditions To be pointed out in this regard is that children often refuse to put on the ear phone and may if opposed react making any conditioning a painstaking business

The investigation can in any case be com pleted another time, repeating the examination in earphones when the child has learnt to co-operate with the examiner

(*b*) Results

With the equipment and by the techniques de scribed, we examined 151 subjects aged between 2 and 5 Our results are given in Table 2.

Table 2. *Results obtained from 151 patients ex amined by way of I C R study*

Age (years)	No. cases	Results: Negative *n*		Indicative *n*		Positive *n*	
2 2½	16	8	50 0	3	18 7	5	31.3
2½–3	23	6	26.1	3	13 0	14	60.9
3–4	60	7	11 6	4	6.7	49	81 7
4–5	5	2	3.8	3	5.8	47	90 4
Total	151	23	15.2	13	8.6	115	76.[illegible]

These results were classified as negative, indicative and positive by the same criteria as reported on page 15. Our data enable us to find the following:

1. The overall proportion of positive results was 76.2%. This result is therefore particularly satisfactory.

2. Indicative results were obtained only in a very small number of patients, i.e., 8.6% of examined cases.

3. The percent number of cases from which useful audiometric data were drawn rises progressively as patients' ages increase, whereas failures were rather infrequent in children over 3 years of age, the percentage of negative results remained relatively high in those of lower age. In subjects between 2 and 2 $^{1}/_{2}$ years of age, particularly, this proportion reached 50% of examined cases.

(e) Considerations

As we see, numerous Authors have used I.C.R. study in audiometric investigations into children. Table 3 gives some data from the literature relative to the percentage of positive results attainable by such investigations into children of varying ages.

The results of our own researches agree essentially with those of earlier Authors as regards both the progressive percent increase of successes in relation to rise in the age of patients and the high incidence of positive results in the groups over 3 years of age.

Our observations (Table 2) show too that the percentage of indicative results obtained with I.C.R. study is very low. This is readily explained when the characteristics of the investigation method are borne in mind. It is evident in fact that the child under test, either understands the relatively simple mechanisms underlying the method and correctly performs the conditioned-reflex movements, enabling the audiogram to be found, or he is not conditioned, and the examination fails.

Table 3 *Results obtained by various Authors through I.C.R. study*

Percentage of cases wherein positive results were achieved

Motta, Facchini & D'Auria		90	82	49	

The highest percentage of indicative results was had in the group of very young children whose restlessness, fatigue or other failure factors already taken into account by us for P.G.R., lessened the probabilities of success in the test.

We must point out, finally, the impossibility of conducting investigations by the above method into children who have severe visual defects. We found this to be the case with two children in whom severe auditory damage was combined with a congenital cataract. Both pathological processes had arisen through measles suffered by the mother during the first months of pregnancy. Investigation through P.G.R. study enabled the hearing threshold to be established with considerable accuracy in these two cases.

3. CONCLUSIONS

Audiometric investigations based on I.C.R. study afford remarkably satisfactory results in children, especially when they are implemented with appropriate skills. The percentage of satisfactory indicative or positive results is noticeably high—around 86%—in children over 3 years old. In lower-aged patients this proportion lowers progressively and drops even to 31% in the group under 2 $^{1}/_{2}$ years of age. It is therefore expedient that more suitable techniques be employed for these patients.

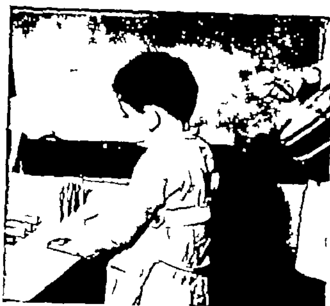

Fig 9 To train the child to react with the right movements to auditory stimuli, his mother or a social assistant can teach him to arrange skittles in a given order at each drum beat.

It is advisable for the child to keep his hand a little away from the pushbutton, so as to prevent him from making too wide and complicated movements. This is especially to be borne in mind with smaller children

Once conditioning is achieved the threshold for the various frequencies is to be sought by reducing the stimulating sound intensity by 10 dB at a time

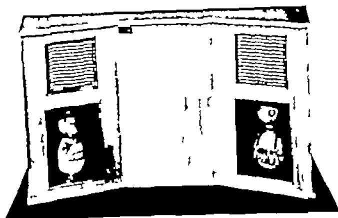
When it is found that a frequency is not heard even at maximum intensity provided by the audiometer it is advisable also to test the neighbouring frequencies, since there may be islands" in correspondence with these wherein the sound stimulus is heard

Sometimes a satisfactory conditioning of the child cannot be achieved during the first session In such event it is preferable, rather than tire or irritate him to suspend the examination and repeat it later—even after only a few hours If despite this precaution, the examination cannot be completed, it will be expedient before persisting further in the tests to instruct the parents in showing the child how to handle different educational toys (blocks, fit-in cylinders etc) after an intense sound stimulation

As an instance the child s mother will be advised to have him arrange skittles in a certain order He will place one skittle at a time as soon as mother gives one beat to a drum (Fig 9) The drum will first be held in front of the child so that he associated the visual with the auditory stimulus Then the visual stimulus must be removed, the drum being placed behind the child and the auditory stimulus sent, taking care that he does not see his mother s hand movement as she beats the drum.

As mentioned, these exercises, which can be done without difficulty with the help of parents, undoubtedly make later audiometric examinations easier since they already establish the child s conditioning to auditory stimuli

It is preferable at the beginning to perform the examination in free field since better cooperation by the child is achieved in these conditions. To be pointed out in this regard is that children often refuse to put on the earphone and may if opposed react, making any conditioning a painstaking business



The investigation can in any case be completed another time, repeating the examination in earphones when the child has learnt to cooperate with the examiner

(b) Results

With the equipment and by the techniques described, we examined 151 subjects aged between 2 and 5 Our results are given in Table 2

Table 2. *Results obtained from 151 patients examined by way of I C R. study*

The results achieved by Suzuki & Ogiba unquestionably demonstrate the validity of their method for audiometric investigations into children under 3 years old. Above this age the Authors, also, noted that the method gives less satisfactory results.

In the course of our own investigations we

CHAPTER 3

Conditioned Orientation Reflexes

1 PREVIOUS RESEARCHES

As we have reported, the audiometric techniques described in the foregoing do not allow sufficiently demonstrative data to be obtained in children under 3 years of age

Indeed both P G.R. study and investigations based on I C.R. *study give rise to a particularly* large number of failures in these subjects as we ourselves have noted

Credit goes to two Japanese, Suzuki & Ogiba for having in 1960 invented an investigation method enabling the number of these failures to be reduced and satisfactory audiometric curves to be plotted in a very high percentage of cases

This method is based on the finding that children when subjected to a sudden light stimulus, turn their heads instinctively towards the light source This is evidently a wholly unconditioned orientation reflex It can however be conditioned by making a sound stimulus precede the luminous one a conditioned orientation reflex (C O R) can thus be achieved for *the auditory stimulus*

The following is the procedure in practice

A light source and a speaker are placed on the patient s right and left side respectively A sound stimulus is first routed on a speaker *and after about 1 sec—still from the same* side—a light stimulus the subject then turns his head towards the sources of the stimuli After these stimulations have been repeated several times, the auditory stimulus only is utilized It is then found that the patient likewise turns his head towards the sound source

To obtain this C O R Suzuki & Ogiba endeavoured to make the light stimulus conform more to the child s interests so that it con*stituted a reward They therefore built a small* theatre (Fig. 10) and fitted a speaker connected to an audiometer to each end In a recess beneath each speaker a plastic doll was placed which could be intensely illuminated by a lamp *located inside the recess*

The controls were set up behind the theatre so that the tone could be routed either to the right or the left speaker and the dolls below lit up simultaneously or otherwise

The child sitting on his mother s lap was placed at the centre of the theatre, at about 50 cm (20 inches) away from it, with his eyes at the level of the dolls The tone was sent into a speaker at an intensity definitely heard by the patient and after 1 sec, the doll below was lit up The same was done on the opposite side After repeating the operation three or four times on both sides of the theatre the child was conditioned, and one proceeded with a simple auditory stimulation The young patient s head turning towards the sound source was proof to the examiner that the stimulus had been heard

The examination was generally performed on four frequencies, the auditory stimulus intensity being reduced 10 dB at a time If a good conditioning was determined the threshold for each of the examined frequencies could be established with relative ease

Ultimately the investigation method put forward by Suzuki & Ogiba does not substantially differ as to theoretical premisses, from that based on I C R study but it lends itself better to researches on smaller children, since it uses

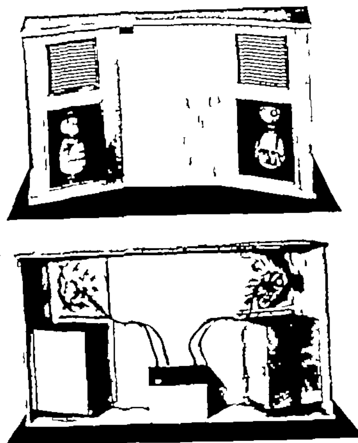

Fig. 10 (A–B). The Suzuki & Ogiba theatre for audiometric examinations by way of C.O.R. study. Note the position of controls and speakers at the rear.

C.O.R. which is more readily established in the child because it involves no co-ordinated activity of the limbs, but merely very simple head movement.

Suzuki & Ogiba examined 115 subjects, obtaining the results given in Table 4. As this table shows, the percentage of positive results rises progressively with age up to 3 years. But as the age goes up further a drop is noted in this percentage. Indeed, the "reward" of dolls lighting up is not enough for older children: in other words, their interest in it quickly flags and this prevents completing the investigation.

The results achieved by Suzuki & Ogiba unquestionably demonstrate the validity of their method for audiometric investigations into children under 3 years old. Above this age the Authors, also, noted that the method gives less satisfactory results.

In the course of our own investigations we

CHAPTER 3

Conditioned Orientation Reflexes

1 PREVIOUS RESEARCHES

As we have reported the audiometric techniques described in the foregoing do not allow sufficiently demonstrative data to be obtained in children under 3 years of age

Indeed both P G R. study and investigations based on I C R. study give rise to a particularly large number of failures in these subjects, as we ourselves have noted

Credit goes to two Japanese, Suzuki & Ogiba, for having in 1960 invented an investigation method enabling the number of these failures to be reduced and satisfactory audiometric curves to be plotted in a very high percentage of cases

This method is based on the finding that children when subjected to a sudden light stimulus, turn their heads instinctively towards the light source This is evidently a wholly unconditioned orientation reflex It can however be conditioned by making a sound stimulus precede the luminous one a conditioned orientation reflex (C O R) can thus be achieved for the auditory stimulus

The following is the procedure in practice

A light source and a speaker are placed on the patient's right and left side respectively A sound stimulus is first routed on a speaker and after about 1 sec—still from the same side—a light stimulus the subject then turns his head towards the sources of the stimuli After these stimulations have been repeated several times, the auditory stimulus only is utilized It is then found that the patient likewise turns his head towards the sound source

To obtain this C O R Suzuki & Ogiba endeavoured to make the light stimulus conform more to the child's interests, so that it constituted a reward They therefore built a small theatre (Fig. 10) and fitted a speaker connected to an audiometer to each end. In a recess beneath each speaker a plastic doll was placed which could be intensely illuminated by a lamp located inside the recess.

The controls were set up behind the theatre so that the tone could be routed either to the right or the left speaker and the dolls below lit up simultaneously or otherwise

The child sitting on his mother's lap was placed at the centre of the theatre, at about 50 cm (20 inches) away from it, with his eyes at the level of the dolls The tone was sent into a speaker at an intensity definitely heard by the patient and after 1 sec, the doll below was lit up The same was done on the opposite side. After repeating the operation three or four times on both sides of the theatre the child was conditioned and one proceeded with a simple auditory stimulation The young patient's head turning towards the sound source was proof to the examiner that the stimulus had been heard

The examination was generally performed on four frequencies the auditory stimulus intensity being reduced 10 dB at a time If a good conditioning was determined the threshold for each of the examined frequencies could be established with relative ease

Ultimately the investigation method put forward by Suzuki & Ogiba does not substantially differ as to theoretical premisses, from that based on I C R study but it lends itself better to researches on smaller children since it uses

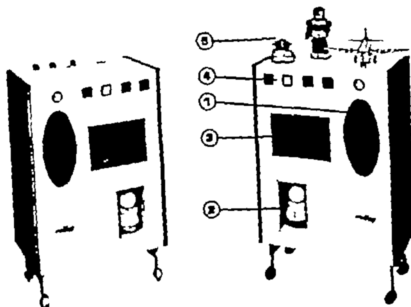

Fig. 12. The Amplifon O 9 Infant Audiology Unit for audiometric investigation via I.C.R. and C.O.R. study. 1. Speaker. 2. Recess with doll for C.O.R. study by the Suzuki & Ogiba technique. 3. Screen for projecting colour transparencies, (for C.O.R. study in older children. I.C.R. study as in the peep-show when the patient controls display of the transparencies by pushbutton linked with the projector. 4. Set of coloured lights (white, green, red ...) for C.O.R. study or to distract patient's glance should it tend to fix upon the opposite-side screen or doll during C.O.R. study. 5. Mechanical toys for I.C.R. study.

the lateral bodies there is, besides the doll, a screen upon which colour transparencies can be projected (Fig. 12).

Depending on patients age and reactive capacity we used either Suzuki & Ogiba's theatre or our own, i.e. Suzuki & Ogiba's for children under 2 years old, for 2 to 3 year-olds, Suzuki & Ogiba theatre or more frequently our own modification, depending on the patient's reactions; our own theatre for children over 3 and in all cases where attention on the dolls exhausted too quickly.

We proceeded as follows in our investigations:

1. The patients were placed in front of the show at a distance of about 30 cm, when the Suzuki & Ogiba equipment was used (Figs. 13 and 14), about 1.70 m, when using our own device (Figs. 15, 16 and 17).

The smaller children were generally held on their mother's or an assistant's lap, the older ones sat in a chair.

2. An auditory stimulus was routed consisting of a tone with frequency and intensity definitely heard by the subject. Immediately about 1 sec after the doll was lighted up or the film and transparencies were projected on to the screen.

Fig. 13. Audiometric examination of 22-month-old by C.O.R. study using the Suzuki & Ogiba theatre.

Fig 11 Show for C.O.R. study Colour transparencies on two screens above the speakers are the reward. Either of the light sources above the screens can distract the child's glance when it fixes upon the opposite-side screen. The show is also utilizable for I.C.R. study in which case the projector is linked to a push-button which depressed by the patient when a sound stimulus is routed, causes images to appear on the screen (cf Figs. 3 and 4).

often had occasion to find that such a draw back can be had even in children under 3 years of age Not infrequently in fact, did we seen patients between 2 and 3 quickly losing interest in the dolls of the Suzuki & Ogiba theatre and this prevented our completing the audiometric examination.

With this in mind we thought it expedient to modify for children over 2 years old the investigation technique put forward by these Authors, by enriching the reward The interest of these subjects in the dolls, in fact, runs out rapidly and the examination should therefore be brief Consequently the number of auditory stimuli that can be routed are insufficient for finding a complete audiogram.

Thus, as our own, Facchini, described in a previous work we used a theatre somewhat larger than the Japanese authors (Fig. 11) It had at each end a speaker and a screen upon which colour transparencies and animated cartoons could be shown by a movie projector located behind The operator was able to route the sound into one of the speakers and show the image simultaneously on the corresponding screen by means of a system of mirrors controlled by a lever The child was then conditioned by using an undeniably more effective reward than dolls The young patient's interest in the colour transparencies and films was indeed very lively and the examination could thus be made longer

Besides proving useful for various 2 to 3 year-old children, this investigation method enabled us to establish the hearing threshold in different older children, between 4 and 5 years of age More specifically these were generally (*a*) either cases where conditioning of instrumental reflexes could not be established owing to character disturbances varying degrees of intelligence deficiency or other reasons, or (*b*) patients with motor deficiencies in the limbs which did not permit using investigation techniques based on I C.R study

Our own theatre could also be used as a peep-show for I C R. study and in fact be linked up with a pushbutton which the small patient operated and set the projector working. It was thus possible in certain cases to change over readily from a C O R. examination to an investigation based on I C R study (Figs. 3 and 4)

Amplifon recently built a theatre for us that takes our findings and experiments over several years of research into account. This is a device similar to Suzuki & Ogiba's but in each of

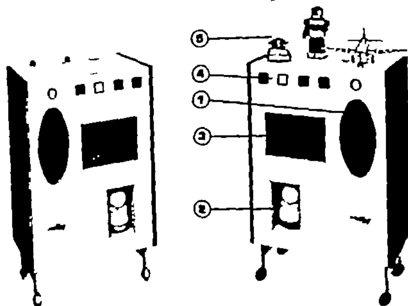

Fig 12. The Amplifon G 9 Infant Audiology Unit for audiometric investigation via I C.R. and C.O.R. study 1 Speaker 2 Recess with doll for C.O R. study by the Suzuki & Ogiba technique. 3 Screen for projecting colour transparencies, affording C.O R. study in older children, I C.R. study as in the peep-show when the patient controls display of the transparencies by a pushbutton linked with the projector 4 Set of coloured lights (white, green, red) for C.O R. study or to distract patient' glance should it tend to fix upon the opposite-side screen or doll during C.O.R. study 5 Mechanical toys for I C.R. study

the lateral bodies there is, besides the doll, a screen upon which colour transparencies can be projected (Fig. 12).

Depending on patients age and reactive capacity we used either Suzuki & Ogiba s theatre or our own, i.e. Suzuki & Ogiba s for children under 2 years old for 2 to 3 year-olds, Suzuki & Ogiba theatre or more frequently our own modification, depending on the patient s reactions our own theatre for children over 3 and in all cases where attention on the dolls exhausted too quickly

We proceeded as follows in our investigations

1 The patients were placed in front of the show at a distance of about 50 cm, when the Suzuki & Ogiba equipment was used (Figs 13 and 14) about 1.0 m, when using our own device (Figs 15 16 and 17).

The smaller children were generally held on their mother s or an assistant s lap the older ones sat in a chair

2 An auditory stimulus was routed consisting of a tone with frequency and intensity definitely heard by the subject. Immediately about 1 sec after the doll was lighted up or the film and transparencies were projected on to the screen

Fig 13 Audiometric examination of 22-month-old by C.O R. study using the Suzuki & Ogiba theatre.

Fig 11 Show for C.O.R. study Colour transparencies on two screens above the speakers are the reward. Either of the light sources above the screens can distract the child's glance when it fixes upon the opposite-side screen. The show is also utilizable for I.C.R. study in which case the projector is linked to a push-button which, depressed by the patient when a sound stimulus is routed, causes images to appear on the screen (cf Figs. 3 and 4).

often had occasion to find that such a draw back can be had even in children under 3 years of age Not infrequently in fact, did we seen patients between 2 and 3 quickly losing interest in the dolls of the Suzuki & Ogiba theatre and this prevented our completing the audiometric examination

With this in mind we thought it expedient to modify for children over 2 years old the in vestigation technique put forward by these Authors by enriching the reward The interest of these subjects in the dolls, in fact, runs out rapidly and the examination should therefore be brief. Consequently the number of auditory stimuli that can be routed are insufficient for finding a complete audiogram

Thus, as our own, Facchini, described in a previous work we used a theatre somewhat larger than the Japanese authors (Fig. 11) It had at each end a speaker and a screen upon which colour transparencies and animated car toons could be shown by a movie projector located behind The operator was able to route the sound into one of the speakers and show the image simultaneously on the corresponding screen by means of a system of mirrors con trolled by a lever The child was then condi tioned by using an undeniably more effective reward than dolls. The young patient s interest in the colour transparencies and films was in-deed very lively and the examination could thus be made longer

Besides proving useful for various 2 to 3 year-old children, this investigation method enabled us to establish the hearing threshold in different older children, between 4 and 5 years of age More specifically these were generally (*a*) either cases where conditioning of instrumental reflexes could not be established owing to character disturbances, varying degrees of intelligence deficiency or other reasons, or (*b*) patients with motor deficiencies in the limbs which did not permit using investigation techniques based on I C.R. study

Our own theatre could also be used as a peep-show for I.C R study and in fact be linked up with a pushbutton which the small patient operated and set the projector working It was thus possible in certain cases to change over readily from a C O R examination to an investigation based on I C R study (Figs. 3 and 4)

Amplifon recently built a theatre for us that takes our findings and experiments over several years of research into account. This is a device similar to Suzuki & Ogiba s, but in each of

rate essential for the over 3-year-olds. In this connection, of course, reactions differ appreciably in the various subjects, in relation also to their psycho-intellectual development.

It is in any case interesting to note that in subjects aged between 3 and 4 the percentage of positive results with audiometry based on C.O.R. study is somewhat higher than is to be found with I.C.R. study.

But the possibilities offered by the two methods are not equal. C.O.R. study does not enable an audiogram to be established for the two single ears, whereas this can be done through I.C.R. study if patients submit to a sufficiently prolonged examination.

These data however demonstrate that in the older children, the two methods integrate one another. Either must be chosen by the examiner allowing not only for the opportunities it offers, but the particular reactivity, co-operation and character attitudes of the child under test.

It was for this reason that we contrived and had Amplifon build an apparatus that allows either investigation method to be adopted (Fig. 12). More specifically, this is a show similar to the Suzuki & Ogiba one. On each of its sides, in addition to the speaker and recess with doll provided with suitable illumination, there is a screen upon which colour transparencies figuring known classical fairy-tale characters can be projected. There are also mechanical toys. Provided, too, are light sources of various colours for distracting the child in the event of his attention being fixed on one of the sides or in special cases, for conditioning the orientation movements. This show affords ready C.O.R. study and yet allows I.C.R. also to be studied, since the appearance of colour images on the screen can be controlled by a pushbutton operated by the child, as in a peep-show.

Embodying within a single unit the devices needed for investigating by way of conditioned reflexes—orientation and instrumental—is undeniably of great advantage to the examiner who is thereby able, after a few attempts, to approach with ease the method to be adopted ... individual case.

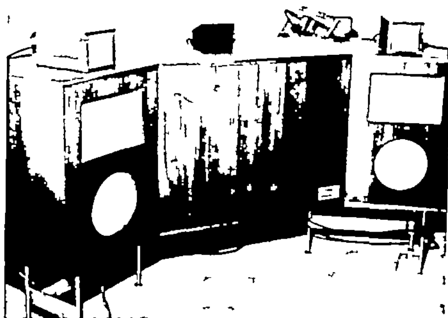

Fig 11 Show for C.O R. study Colour transparencies on two screens above the speakers are the reward. Either of the light sources above the screens can distract the child's glance when it fixes upon the opposite-side screen. The show is also utilizable for I.C.R. study in which case the projector is linked to a push-button which, depressed by the patient when a sound stimulus is routed, causes images to appear on the screen (cf Figs. 3 and 4).

Amplifon recently built a theatre for us that takes our findings and experiments over several years of research into account. This is a device similar to Suzuki & Ogiba s, but in each of

Fig 16 Audiometric examination of a year old by C.O.R. study using a show with screens displaying colour transparencies.

leave doubt as to the actual existence of the orientation reflex.

4 Conditioning obtained, the sound stimulus was routed without following it with the visual, and turning of the patient's head towards the sound source was observed The operation was repeated, reducing the sound-stimulus intensity progressively by 10 dB at a time so as to establish the threshold for each frequency

5 In order to be sure of the extent of the tone range of sounds which had apparently not been heard in that they gave rise to no orientation reflex, these were routed at the maximum intensity afforded by the audiometer in rapid succession so as rule out possible reactions on the part of the subject. The threshold of the highest frequency heard by the patient was confirmed in addition. The following was the procedure in practice

If for instance, the last reflex reaction had been had for a 1 000 c s frequency sound at 90 dB, sound stimuli of 4 000, 3 000 and 000 c at 170 dB and of 1 000 c s a 90 dB were routed in quick succession. If in effect sound stimuli of frequencies over 1 000 c were not perceived, it was found that the child turned his head quickly towards the sound source when the last auditory stimulus was emitted.

These skills are unquestionably important for correctly defining residual hearing, necessary for fitting the patient possibly with a hearing aid and for the approach to his speech training

Fig 17 A 3-year-old examined audiometrically by C O R. study using a show with screens on to which colour transparencies are projected.

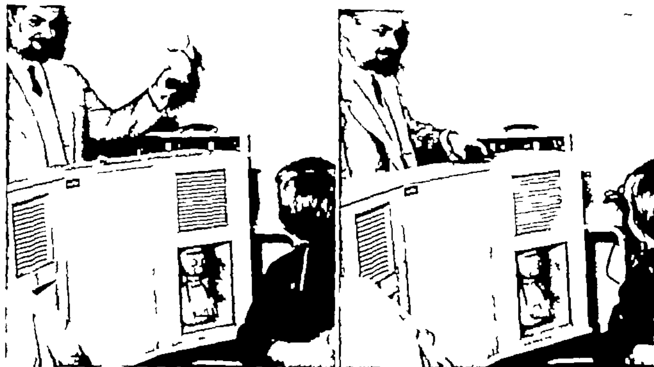

Fig 14 Audiometric examination by C.O R. study using the Suzuki & Ogiba theatre. We prefer first to investigate one side then the opposite But after a few stimulations the child's glance generally tends to fix upon the side where the sounds originate This prevents continuing the study of orientation reflexes to this side The drawback can be overcome by attracting patient s attention to a small toy getting him to turn his head towards the opposite side.

3 The operation was repeated several times until achieving the conditioning of head turning movements or orientation on the sound source

We always took care in this connection to check eye-ball as well as head-orientation movements, since these can take on considerable importance in some cases where turning of the cephalic extreme being barely perceptibl may

of these Authors, however the percentage of satisfactory results remained high even in our group of patients over 3 years old. Indeed, the positive results reached 85% in these subjects and there were no failures.

(c) **Considerations**

Our own observations above all demonstrate the importance of C.O.R. study in audiometric investigations into children under 3 years of age

This investigation method indeed appears to be decidedly more advantageous in these patients than the one based on I.C.R. study affording a much higher percentage of positive results, a a comparison between Tables 5 and clearly shows.

Our studies also demonstrate that when suitable modifications are brought to the examination method and technical equipment put forward by *Suzuki & Ogiba, the percentage of* positive results remains ery high even in patients over 3 years old In these cases it is essential during investigations to provide the small patient with a "reward that is more satisfying to him and holds his interest better than the original Suzuki & Ogiba theatre dolls.

For this reason, for investigations into children a little older we modified the Suzuki & Ogiba device by replacing the dolls with two screens upon which colour transparencies or animated cartoons were projected.

This technique often appears to be useful also for children aged – ½ to 3 It is at any rate essential for the over 3-year-olds. In this connection, of course, reactions differ appreciably in the various subjects in relation also to their psycho-intellectual development.

It is in any case interesting to note that in subjects aged between 3 and 4 the percentage of positive results with audiometry based on C.O.R. study is somewhat higher than is to be found with I.C.R. study

But the possibilities offered by the two methods are not equal. C.O.R study does not enable an audiogram to be established for the two single ears, whereas this can be done through I.C.R. study if patients submit to a sufficiently prolonged examination.

These data however demonstrate that in the older children, the two methods integrate one another Either must be chosen by the examiner allowing not only for the opportunities it offers, but the particular reactivity co-operation and character attitudes of the child under test.

It was for this reason that we contrived and had Amplifon build an apparatus that allows either investigation method to be adopted (Fig. 12). More specifically this is a show similar to the Suzuki & Ogiba one On each of its sides, in addition to the speaker and recess with doll provided with suitable illumination, there is a screen upon which colour transparencies figuring known classical fairy-tale characters can be *projected*. There are also mechanical toys. Provided, too, are light sources of various colours for distracting the child in the event *of his attention being fixed* on one of the sides or in special cases, for conditioning the orientation movements. This show affords ready C.O.R. study and yet allows I.C.R. also to be studied, since the appearance of colour images on the screen can be controlled by a pushbutton *operated by the child*, as in a peep-show

Embodying within a single unit the devices needed for investigating by way of conditioned *reflexes*—orientation and instrumental—is undeniably of great advantage to the examiner *who is* thereby able after a few attempts, to approach with ease the method to be adopted in each individual case.

We draw attention, finally to the expediency often met with in our small patients—especially when displaying hearing handicaps—of conducting investigations first into one side then into the opposite one, rather than both at once.

To be pointed out above all is that the normal hearing child has a certain facility for correctly locating the direction of a sound, even when the source is shifted from right to left, and vice versa But the child with hearing handicaps often displays considerable stiffness in reactions and tends always to turn in the direction of the first stimulus This kind of response is of course more apparent when the patient has marked differences in hearing capacity between the two ears There are undoubtedly also deaf children who after brief training tend to orientate correctly on the direction of the two sound stimuli. But very often during the first consulting room examination bilateral conditioning engenders confusion in the small patient and he consequently gives wrong responses as to the sound direction Moreover in an attempt to earn the reward he frequently tends to turn his head to the right and left before the sound stimulus is routed He thus becomes agitated and his behaviour is dispersive for the purposes of the test.

To overcome these drawbacks—and bearing in mind that the normal C O R technique is based on bilateralness of the stimuli—we attempted to condition patients on one side only introducing a disturbance visual stimulus In practice our procedure was as follows

(i) If the Suzuki & Ogiba theatre was used, the examiner at the start of investigation placed himself in front of the subject, beyond the theatre itself (Fig. 14) He kept a small rubber toy or railway engine handy He then proceeded to condition the child on the doll of one side—the left, *for instance* At a given moment the patient fixed his glance on this side in order to see the doll light up The examiner then distracted his attention by showing him the rubber toy or engine which were slowly moved from left to right of the theatre stage Interested in the new toy the child turned his head to the right The auditory signal was routed at this point and, if it was heard, the child was seen to turn his head to the left again

We used different toys to distract the patient, ensuring that these were not more stimulating than the Suzuki & Ogiba lighted-up doll We also took care to execute the movements tending to distract the child *at a certain speed so* that his interest remained concentrated on the doll This was to avoid his no longer co-operating in the investigation through attention being drawn to the new toy

(ii) If it was a case of older patients, for whom the modified show equipped with projector was utilized, the child was conditioned by getting him to look at the film or colour transparencies on the screen of one side only the left, for example At a given point, when he had fixed his glance on the screen waiting for the animated cartoons to appear the examiner lit up a particularly bright lamp on the right, screened by frosted glass (Figs 11 12 4 15 16 and 17) situated on the surface of the device itself. The subject was thereby distracted, and instinctively turned to the right. At this juncture the auditory signal was given on the left and any head turning toward this side was observed.

(*b*) Results

Our investigations utilizing the procedures we have described, involved 130 subjects from 1 to 4 years old

Our results are given in Table 5 They are classified as negative, indicative and positive by the same criteria as in page 15

When the results we obtained through C O R study are taken overall one first finds that the failure percentage by this method is really low indeed not coming up to 10% of examined cases.

The data in Table 5 further demonstrate that the percentage of positive results rose progressively with the age of patients, as Suzuki & Ogiba also found As opposed to the findings

Table 5 *Results obtained for 130 patients examined through C.O.R. study*

Age (years)	No. cases	Results					
		Negative		Indicativ		Positive	
			%				%
1–1½	21	4	19.0	6	28.6	11	52.4
1½–2	26	3	11.5	8	30.8	15	57.7
2–2½	32	3	9.4	7	21.9	22	68.
2½–3	31	2	6.5	5	16.1	24	77.4
3–4	20	0	0	3	15.0	17	85.0
Total	130	12	9.2	29	22.3	89	68.5

of these Authors, however the percentage of satisfactory results remained high even in our group of patients over 3 years old. Indeed, the positive results reached 85% in these subjects, and there were no failures

(*e*) Considerations

Our own observations above all demonstrate the importance of C.O.R. study in audiometric investigations into children under 3 years of age.

This investigation method indeed appears to be decidedly more advantageous in these patients than the one based on I.C.R. study affording a much higher percentage of positive results, as a comparison between Tables 5 and 2 clearly shows.

Our studies also demonstrate that when suitable modifications are brought to the examination method and technical equipment put forward by Suzuki & Ogiba, the percentage of positive results remains very high even in patients over 3 years old. In these cases it is essential during investigations to provide the small patient with a "reward" that is more satisfying to him and holds his interest better than the original Suzuki & Ogiba theatre dolls.

For this reason, for investigations into children a little older we modified the Suzuki & Ogiba device by replacing the dolls with two screens upon which colour transparencies or animated cartoons were projected.

This technique often appears to be useful also for children aged 2 ½ to 3 It is at any rate essential for the over 3-year-olds. In this connection, of course, reactions differ appreciably in the various subjects, in relation also to their psycho-intellectual development.

It is in any case interesting to note that in subjects aged between 3 and 4 the percentage of positive results with audiometry based on C.O.R. study is somewhat higher than is to be found with I.C.R. study

But the possibilities offered by the two methods are not equal. C.O.R study does not enable an audiogram to be established for the two single ears, whereas this can be done through I.C.R. study if patients submit to a sufficiently prolonged examination.

These data however demonstrate that in the older children, the two methods integrate one another Either must be chosen by the examiner allowing not only for the opportunities it offers, but the particular reactivity co-operation and character attitudes of the child under test.

It was for this reason that we contrived and had Amplifon build an apparatus that allows either investigation method to be adopted (Fig. 12). More specifically this is a show similar to the Suzuki & Ogiba one. On each of its sides, in addition to the speaker and recess with doll provided with suitable illumination, there is a screen upon which colour transparencies figuring known classical fairy-tale characters can be projected. There are also mechanical toys. Provided, too, are light sources of various colours for distracting the child in the event of his attention being fixed on one of the sides or in special cases, for conditioning the orientation movements. This show affords ready C.O R. study and yet allows I.C.R also to be studied, since the appearance of colour images on the screen can be controlled by a pushbutton operated by the child, as in a peep-show

Embodying within a single unit the devices needed for investigating by way of conditioned reflexes—orientation and instrumental—is undeniably of great advantage to the examiner who is thereby able, after a few attempts, to approach with ease the method to be adopted in each individual case.

We draw attention, finally to the expediency often met with in our small patients—especially when displaying hearing handicaps—of conducting investigations first into one side then into the opposite one, rather than both at once

To be pointed out above all is that the normal hearing child has a certain facility for correctly locating the direction of a sound, even when the source is shifted from right to left, and vice versa. But the child with hearing handicaps often displays considerable stiffness in reactions and tends always to turn in the direction of the first stimulus This kind of response is of course more apparent when the patient has marked differences in hearing capacity between the two ears There are undoubtedly also deaf children who after brief training tend to orientate correctly on the direction of the two sound stimuli But very often during the first consulting-room examination, bilateral conditioning engenders confusion in the small patient and he consequently gives wrong responses as to the sound direction Moreover in an attempt to earn the reward he frequently tends to turn his head to the right and left before the sound stimulus is routed He thus becomes agitated and his behaviour is dispersive for the purposes of the test.

2½–3	31	2	6.5	5	16.1	4	77.4
3–4	20	0	0	3	15.0	17	85.0
Total	130	12	9.2	29	22.3	89	68.5

of these Authors, however the percentage of satisfactory results remained high even in our group of patients over 3 years old. Indeed, the positive results reached 85% in these subjects, and there were no failures.

(c) Considerations

Our own observations above all demonstrate the importance of C.O.R. study in audiometric investigations into children under 3 years of age.

This investigation method indeed appears to be decidedly more advantageous in these patients than the one based on I.C.R. study affording a much higher percentage of positive results, as a comparison between Tables 5 and 2 clearly shows.

Our studies also demonstrate that when suitable modifications are brought to the examination method and technical equipment put forward by *Suzuki & Ogiba*, the percentage of positive results remains very high even in patients over 3 years old. *In these cases it is es*sential during investigations to provide the small patient with a "reward" that is more satisfying to him and holds his interest better than the original Suzuki & Ogiba theatre dolls.

For this reason, for investigations into children a little older we modified the Suzuki & Ogiba device by replacing the dolls with two screens upon which colour transparencies or animated cartoons were projected

This technique often appears to be useful also for children aged 2½ to 3 It is at any rate essential for the over 3-year-olds. In this connection, of course reactions differ appreciably in the various subjects, in relation also to their psycho-intellectual development.

It is in any case interesting to note that in subjects aged between 3 and 4 the percentage of positive results with audiometry based on C.O.R. study is somewhat higher than is to be found with I.C.R. study

But the possibilities offered by the two methods are not equal. C.O.R. study does not enable an audiogram to be established for the two single ears, whereas this can be done through I.C.R. study if patients submit to a sufficiently prolonged examination.

These data however demonstrate that in the older children, the two methods integrate one another Either must be chosen by the examiner allowing not only for the opportunities it offers, but the particular reactivity co-operation and character attitudes of the child under test.

It was for this reason that we contrived and had Amplifon build an apparatus that allows either investigation method to be adopted (Fig. 12) More specifically this is a show similar to the Suzuki & Ogiba one. On each of its sides, in addition to the speaker and recess with doll provided with suitable illumination, there is a screen upon which colour transparencies figuring known classical fairy-tale characters can be projected. There are also mechanical toys. Provided, too are light sources of various colours for distracting the child in the event of his attention being fixed on one of the sides or in special cases, for conditioning the orientation movements. This show affords ready C.O.R. study and yet allows I.C.R. also to be studied, since the appearance of colour images on the screen can be controlled by a pushbutton operated by the child, as in a peep-show

Embodying within a single unit the devices needed for investigating by way of conditioned reflexes—orientation and instrumental—is undeniably of great advantage to the examiner who is thereby able, after a few attempts, to approach with ease the method to be adopted in each individual case.

We draw attention finally to the expediency *often met with in our small patients*—especially when displaying hearing handicaps—of conducting investigations *first* into one side, then into the opposite one rather than both at once

To be pointed out above all is that the normal hearing child has a certain facility for correctly locating the direction of a sound, even when the source is shifted from right to left, and vice versa But the child with hearing handicaps often displays considerable stiffness in reactions, and tends always to turn in the direction of the first stimulus This kind of response is of course more apparent when the patient has marked differences in hearing capacity between the two ears There are undoubtedly also deaf children who after brief training tend to orientate correctly on the direction of the two sound stimuli But very often during the first consulting-room examination bilateral conditioning engenders confusion *in the small* patient and he consequently gives wrong responses *as to the sound direction Moreover* in an attempt to earn the reward he frequently *tends to turn his head to the right and* left before the sound stimulus is routed He thus becomes agitated and his behaviour is dispersive for the purposes of the test

To overcome these drawbacks—and bearing in mind that the normal C O R. technique is based on bilateralness of the stimuli—we attempted to condition patients on one side only introducing a disturbance visual stimulus In practice our procedure was as follows

(i) If the Suzuki & Ogiba theatre was used, the examiner at the start of investigation placed himself in front of the subject, beyond the theatre itself (Fig 14) He kept a small rubber toy or railway engine handy He then proceeded to condition the child on the doll of one side—the left for instance At a given moment the patient fixed his glance on this side in order to see the doll light up The examiner then distracted his attention by showing him the rubber toy or engine which were slowly moved from left to right of the theatre stage Interested in the new toy the child turned his head to the right The auditory signal was routed at this point and if it was heard, the child was seen to turn his head to the left again

We used different toys to distract the patient, ensuring that these were not more stimulating than the Suzuki & Ogiba lighted-up doll We also took care to execute the movements tending to distract the child at a certain speed, so that his interest remained concentrated on the doll. This was to avoid his no longer co-operating in the investigation through attention being drawn to the new toy

(ii) If it was a case of older patients, for whom the modified show equipped with projector was utilized, the child was conditioned by getting him to look at the film or colour transparencies on the screen of one side only the left, *for* example At a *given point*, when he had fixed his glance on the screen waiting *for the animated cartoons to appear* the examiner lit up a particularly bright lamp on the *right, screened by frosted glass* (Figs. 11 12. 4 15 16 and 17) situated on the surface of *the device itself The subject was thereby* distracted and instinctively turned to the right. At this juncture *the auditory signal was given* on the left, and any head-turning toward this side was observed

(*b*) Results

Our investigations, utilizing the *procedures we* have described, involved 130 subjects from 1 to 4 years old

Our results are given in Table 5 They are classified as negative indicative *and positive* by the same criteria as in page 15

When the results we *obtained through C O R* study are taken overall one first finds that the failure percentage by this *method is really low* indeed, not coming up to 10% of examined cases

The data in Table 5 further demonstrate that the percentage of positive *results rose progressively* with the age of patients, as Suzuki & Ogiba also *found As opposed to the findings*

Table 5 *Results obtained for 130 patients examined through C.O.R. study*

Age (years)	No. cases	Results: Negative	%	Indicative		Positive	%
1–1½	21	4	19.0	6	28.6	11	52.4
1½–2	26	3	11.5	8	30.8	15	57.7
2½	32	3	9.4	7	21.9	22	68.7
2½–3	31	2	6.5	5	16.1	24	77.4
3–4	20	0	0	3	15.0	17	85.0
Total	130	12	9.2	29	22.3	89	68.5

of these Authors, however the percentage of satisfactory results remained high even in our group of patients over 3 years old. Indeed, the positive results reached 85% in these subjects, and there were no failures.

(*c*) Considerations

Our own observations above all demonstrate the importance of C.O.R. study in audiometric investigations into children *under 3 years of age.*

This investigation method indeed appears to be decidedly more advantageous in these patients than the one based on I.C.R. study affording a much higher percentage of positive results, as a comparison between Tables 5 and 2 clearly shows.

Our studies also demonstrate that when suitable modifications are brought to the examination method and technical equipment put forward by Suzuki & Ogiba, the percentage of positive results remains very high even in patients over 3 years old. In these cases *it is essential* during investigations to provide the small patient with a reward that is more satisfying to him and holds his interest better than the original Suzuki & Ogiba theatre dolls.

For this reason, for investigations into children a little older we modified the Suzuki & Ogiba device by replacing the dolls with two screens upon which colour transparencies or animated cartoons were projected.

This technique often appears *to be useful* also for children aged 2 / to 3 It is at any rate essential for the over 3-year-olds. In this connection, of course reactions differ appreciably in the various subjects, in relation also to their psycho-intellectual development.

It is in any case interesting to note that in subjects aged between 3 and 4 the percentage *of positive results with audiometry based on* C.O.R. study is somewhat higher than is to be found with I.C.R. study

But the possibilities offered by the two methods are not equal. C.O.R. study does not enable an audiogram to be established for the two single ears, whereas this can be done through I.C.R. study if patients submit to a sufficiently prolonged examination.

These data however demonstrate that in the older children the two methods integrate one another Either must be chosen by the examiner allowing not only for the opportunities it *offers*, but the particular reactivity co-operation and character attitudes of the child under test.

It was for this reason that we contrived and *had Amplifon build* an apparatus that allows either investigation method to be adopted (Fig. 12). More specifically this is a show similar to the Suzuki & Ogiba one. On each *of its* sides, in addition to the speaker and recess with doll provided with suitable illumination, there is a screen upon which colour transparencies figuring known classical fairy-tale characters can be projected. There are also mechanical toys. Provided, too, are light sources of various colours for distracting the child in the event of his attention being fixed on one of the sides or in special cases, for conditioning the *orientation movements*. This show affords ready C O R. study and yet allows I.C.R. also to be studied, since the appearance of colour images on the screen can be *controlled* by a pushbutton operated by the child, as in a peep-show

Embodying within a single unit the devices needed for investigating by way of *conditioned* reflexes—orientation and instrumental—is undeniably of great advantage to the examiner who is thereby able, after a few attempts, to approach with ease the method to be adopted in each individual case

3 CONCLUSIONS

Our observations show that the most suitable investigation method for establishing the audiometric curve in children under 4 years old is the one based on C O R. study

This investigation has to be conducted by adapting the technique to the child's age, his mental development and psychomotor reactions More specifically the theatre designed by Suzuki & Ogiba perfectly meets the needs of the investigation in smaller children Over 3 years of age, however the child s interest in the Suzuki & Ogiba dolls tends quickly to exhaust itself and this often necessitates bringing the reward" into line by more interesting games For this reason we used a show similar to Suzuki & Ogiba s, but wherein colour transparencies or animated cartoons can be projected

In older children—and especially those between 3 and 4 years of age—it can be established each time depending on their reactions, whether it is preferable to use this show or I C.R study Both techniques in fact enable a high percentage of positive results to be achieved although each has its advantages and disadvantages More specifically

1 C.O.R. study affords positive good or indicative results in the totality of examined cases. It is not possible however to explore the auditory capacity of the two ears singly by this method

2 I C.R study though giving rise to a larger number of failures, nevertheless allows an audiogram to be plotted for each ear in cases where good conditioning can be established and the examination prolonged sufficiently

We therefore proposed a device and had it built by Amplifon for audiometric investigations into children that enables both techniques to be performed thereby giving the examiner the opportunity to select the more appropriate one, taking examination demands and patients capacity for co-operation into account

Appendix

OBJECTIVE CONDITIONED-REFLEX AUDIOMETRY IN MULTI HANDICAPPED CHILDREN

1 Premises

Audiometric investigations into children unquestionably present sizable difficulties if, besides any hearing disability there are psycho-intellectual alterations or handicaps in skeletal motility or yet impairment of different sensorial apparata. The existence of pathological situations of this kind can make the child's conditioning very complicated indeed, and hinder the audiometric investigations we have described in the foregoing.

In these conditions the researches that aim at establishing the existence or otherwise of an auditory deficiency cannot generally be conducted within the short space of time demanded by a consulting-room investigation as defined at the beginning of this work. It is usually necessary to proceed with a lengthy series of observations over a period of time and with the co-operation of the neurologist, psychologist, teacher and phoniatrician.

Only in this way will effective collection be made of all the data affording precise identification of the various sensorial, intellectual, mental and motor handicaps presented by the patient, and accurate framing of the clinical case. It will then be possible to direct the patient to centres where he will be given the most efficient help and correct training be implemented.

We ourselves are often faced with typical situations in current practice i.e., we are asked either to examine children whose hearing is certainly impaired and who have other handicaps, and it is wished to know the extent of their auditory deficiency or to establish whether or not certain multi-handicapped subjects displaying psycho-intellectual disturbances have impaired auditory function, and what part this has played in retarding their mental development.

We took four groups of subjects into account in our survey. We think the investigation procedures adopted in each of these groups and the technical skills employed in the individual cases described, give a clear enough idea both of the difficulties involved in such researches and of the facilities we have for overcoming them.

2 Personal researches

The groups seeming most representative to us are made up of:

(a) Subjects with disturbances in symbolic function
(b) Mentally handicapped subjects with low I.Q
(c) Spastic or athetosic subjects
(d) Subjects multi-handicapped through foetal virosis contracted by mother during early months of intrauterine life

(a) *Subjects with disturbances in symbolic function*

These are subjects who, through alteration of certain cortical centres and resultant impairment of integrating capacity present difficulty or outright impossibility in organizing all the psychomotor activities underlying speech.

These patients have been defined as aphasic oid (Myklebust; Coen Rosen etc.) or even dysgnosic (Prélot & Lafon). Audiometric investigation into these cases always presents considerable difficulty.

The main difficulty the audiologist has to tackle is that children with such handicaps cannot usually manage to understand the prob-

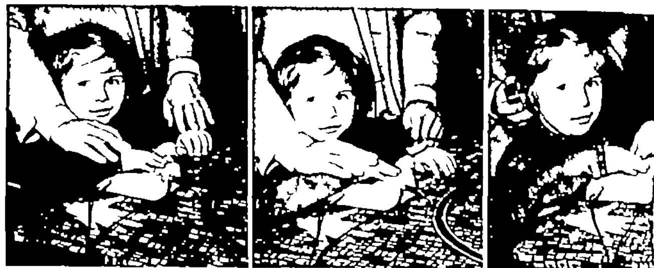

Fig 18 Audiometric examination by I C.R study of a child with symbolic function disorders. To get her to understand the relation between electric train movements and auditory stimulus, conditioning was done over successive periods. The bone vibrator was first placed in contact with the palm, then on the wrist and finally on the mastoid, at which stage the patient was conditioned by a sound-tactile stimulus. Conditioning established the vibrator was replaced by an earphone thereby suppressing the tactile stimulus.

lem of I C R. audiometry Consequently it is impossible to establish correct conditioning.

These patients in fact, generally fix their whole attention upon a toy but do not link its movement possibilities with the tone present in the speaker and with pressure on the button They therefore remain wholly inert during the various stages of the examination, or press the button connected with the toy whether the sound is present in the speaker or not. Only in rare cases particularly favourable to the investigation is it observed that any time he hears the tone the child watches the toy hoping for it to move spontaneously This reaction is undoubtedly in itself information useful to the examiner

Generally therefore it is found that the tone by air conduction is not a stimulus of adequate intensity for these patients i e such as to draw their attention. Even when the hearing loss is slight they often fail to react also to stimuli of marked intensity (90–100 dB on frequencies between 125 and 500 c/s)

Frisina & Bernero pointing out the scant possibilities of establishing conditioning in many of these patients of pre-school age with the use of pure tones by air conduction proposed applying a bone vibrator to the fit-together toy they used for examining children by play-audiometry Their procedure was as follows.

A 500 c/s tone at 50–70 dB was first routed into the vibrator and the child under test was trained to perceive the tactile stimulus and move the toy to build a tower every time the stimulation was given. The vibrator was then transferred to the child's palm, his wrist and lastly to his mastoid. At this stage the tactile stimulus was necessarily combined with a sound stimulus which the patient received by bone conduction The examination then proceeded by placing the child's palm on an audiometer earphone into which a 500 c/s tone at 100 dB was routed. Once the child was conditioned by this new tactile-vibratory stimulation the examination continued by transferring the earphone to the ear The child could then be observed to react correctly also to the sound stimulus alone

After using the Frisina & Bernero technique for about two years we chose to modify it with a view to bettering its results More specifically in *free field examinations* we employed I C.R. study with either of the following methods, depending on the small patient s reactions.

Method I After placing the bone vibrator under the child's palm we conditioned him so he would be induced to depress the button linked to the toy each time the tone was routed into the vibrator We then placed the vibrator in contact with his wrist, and finally on the mastoid (Fig. 18). The child was con

ditioned by the sound as well as the tactile stimulus during the latter stage. When sure that the conditioning was well established, we removed the vibrator and routed the auditory stimulus alone on the speaker. While enabling us to achieve good results in several patients, this method sometimes presented drawbacks, i.e. (*a*) The small patient was at times afraid to keep his hand resting on the bone vibrator even when before starting the investigation the examiner showed him how harmless it was by placing his own hand upon it;
(*b*) Once the tactile-vibratory stimulus was removed and the tone routed by air conduction, the child often remained indifferent to the new stimulation.

Method II To overcome these drawbacks we chose the following procedure for some patients. The child put his palm directly on speaker into which grave-frequency sound was routed (we generally used a 250 or 500 / tone at 80 dB). H was then induced to depress the pushbutton operating the toy each time he perceived the tactile-vibratory stimulus and heard the sound (Fig. 19). The child's conditioning was achieved more easily by using these different stimuli simultaneously and, chiefly he could be made to understand that an association existed between stimuli and toy movements. Once a satisfactory conditioning was obtained, the speaker was placed in front of the child, and the examination proceeded with the sound stimulus alone. Often when he heard the tone, the child sought tactile confirmation of its presence, and brought his hand on to the speaker to ascertain its vibration.

I our view this second modification offers several advantages over the method based on bone vibrator and in fact it enables stimulus by air conduction to be combined with the tactile-vibratory stimulus used initially. It is thus possible to pass more readily on to the second stage of the investigation, where the air-conduction stimulus only will be used it voids any particular fright reaction, in small children as ell

As Frisina & Bernero mentioned, in the case of *examinations in earphone* it is undeniably ery useful to associate in the child's mind a relationship between tactile-vibratory and sound stimulus. To do this it is expedient first to place the child's palm on the earphone into which the tone is routed (preferably a 500 c s sound at 90 dB), so that he becomes conditioned to react by depressing the button that sets the toy in motion each time he is stimulated.

Some cases studied by us far better illustrate the possibilities and limitations of these audiometric investigation methods.

Case 31 Age 6 years. Born at term. Weight 3.8 kg. Jaundice of moderate entity at birth, lasting 5–6 days. No exchange transfusion.

Fig. 19 A low I.Q. patient examined audiometrically by I.C.R. study. As in Fig. 18 he was first conditioned by a tactile-sound stimulus, getting him to place his palm on the speaker. Conditioning established, the tactile stimulus was suppressed and the examination proceeded in free field.

Neurological findings: considerable general hypotonia and difficulty in feeding during first month. Extreme retardation in walking (started at 30 months). Neurological examination revealed hyperreflexia and bilateral hint of a Babinski.

E.E.G.: signs of distress of deep origin, with irritative aspects.

At the age of 6 his I.Q. by Borelli-Oleron test fluctuates between 0.55 and 0.60. Marked degree of phrenasthenia. Extreme difficulty in structuring very simple forms. No possibility of graph, this is at the prefiourage stage.

Speech: first words spoken when 3 / years old. Child says "babbo, mamma, nonna, bimbo (papa, mama, grandma, baby) and few other words of incomprehensible phonetic structure.

Audiometric investigation: enormous difficulty encountered in conditioning child with pure tones; besides poorly understanding the problem of relations between sound stimulus and toy movement, he presents

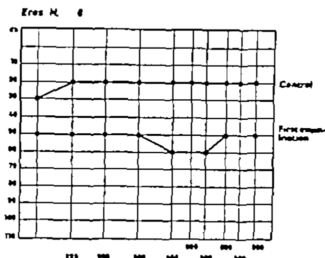

Fig 20 (*Eros M* aged 6.) Patient aphasic through neonatal jaundice. Audiometric examination was by I.C.R. study in free field. There is an evident flucting hearing. The first examination revealed a hearing *loss of about 50 dB Control after 10 days* established the loss to be very modest

flucting-hearing, giving conflicting responses as to the hearing threshold for sound stimuli, even when spaced 40–50 dB from one another On the whole however the data obtained lead to suppose that a moderate hearing capacity exists.

After repeated tests, initially getting his hand to rest *upon the speaker then conducting the investiga* tion in free field his conditioning was managed.

The first audiogram so executed enabled the hearing threshold to be located at a level of about 50 dB A control after 10 days established the patient's hearing *loss* to be very moderate and not exceeding 20 dB (Fig. 20).

Present behaviour subject still extremely distracted, paying no particular attention to the world around him. He seems able at times to understand not-too-complicated speech like andiamo via (let's go) or andiamo dalla nonna (let's go to grandma's) at *others he reacts to no oral stimulus*. He does not supplement his lack of speech with gestures. If he does not manage to get what he wants, he is taken by attacks of temper accompanied by crying.

The child is under training at the Bologna Municipal *Orthophonic Centre His possible scholastic* progress is unassessable at the moment

Silvana T Age 9 years. Born at term. Weight 3 2 kg. Severe jaundice from materno-foetal incompatibility *of the Rh system, breaking out 4 days after birth and* lasting 40 No exchange transfusion.

Neurological findings. somnolence and grave difficulty in feeding during first months after birth A high degree of general hypotonia also present whereby patient succeeded *in sitting up at 10–11 months and* began walking at 14 months.

E.E.G moderate diffuse irritative signs.

At the age of 9 her I.Q defined by the Terman test is 0 60. *Speech and arithmetic tests*, even for 5 year-olds, were negative. The Wisc blocks tests was moderately well resolved in relation patient's age. The Bender test revealed her to be sufficiently structured for her age

Speech. the child presented severe retardation in speech development. Up to the age of 4 she uttered few words with evident dyslalia. Her education had been approached wrongly on the assumption that more-or less severe deafness existed, she was first sent to a school for the hard-of-hearing. In this environment, where she was scarcely impelled to talk, *her speech suffered a further blockage. She remained* practically mute for many months. Despite her mother's assertion that the child's hearing was normal, the teacher and specialist were unable to realize that this was so. The specialist, in particular was deceived by her passive behaviour during audiometric examinations, and by the wrong responses she gave. The teacher on the other hand, influenced by long experience of untrue or inaccurate anamnestic data furnished by relatives, was also led into error by the child's particular behaviour

Audiometric investigation the patient presented *marked flucting-hearing. During the first tests she* did not even respond systematically to stimulations by 1 000, 2 000 and 3 000 c/s tones routed at 100 dB leading one to presume a severe deficiency on the conversation voice frequencies. Subsequent in*vestigations, conducted by the procedures we have* described, enabled the patient to be conditioned satisfactorily and established her hearing to be practically normal (Fig. 21)

Present behaviour when it was realized that the patient's hearing was normal she was transferred to

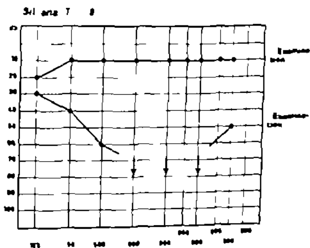

Fig 21 (*Silvana T* aged 9) Patient aphasic through severe neonatal jaundice *from materno-foetal incom*patibility of Rh system. Audiometric examination was by free-field I.C.R. study The findings first led a severe auditory deficiency to be presumed Subsequent examinations by appropriate techniques disclosed a nearly normal *hearing capacity*

a school for the mentally handicapped. Her speech has developed, but it remains severely dyslalic and imprecise. She says "papa" for "zio" (uncle), "sera" (evening) for "mattina" (morning). She learns a word and easily forgets it. She often breaks off the conversation through not knowing the necessary words for completing it.

Her behaviour is still scarcely socialized, unstable and dependent. She is incapable of dressing or undressing herself, often collides with desks and seems absent.

(b) *Mentally handicapped subjects with low I Q*

Many of the skills employed in subjects with symbolic-function disorders, and described in the foregoing paragraph, can often also be advantageous for low I.Q. patients to achieve a good conditioning of instrumental reflexes and so use the study of these to find the audiogram.

It is to be pointed out at once, however, that the study of instrumental reflexes and generally of play-audiometry is only possible when patients with I.Q. over 50 are examined. According to some authors (Prélot & Lafon) and to our own experience, the attempts to establish conditioning of instrumental reflexes in children with I.Q. lower than this value are generally attended by failure and it is therefore definitely preferable to use C.O.R. study in these cases.

By adopting these approaches we could resolve—sometimes at one session only—cases that might have taken several days of observation or induced the examiner to postpone the test for a few years.

We must nevertheless mention that, in conflict with every technical forecast, the gravity of the handicaps is sometimes such as to render fruitless all attempts at establishing the characteristics of the possible hearing deficiency.

Sauro E. Age 13 years. Born at eighth month. Weight 1.8 kg.

Severe jaundice from materno-foetal incompatibility of the Rh system, arising 10 days after birth, with clear signs of intolerance to mother's milk and convulsive episodes.

Neurological findings: frequent convulsive attacks

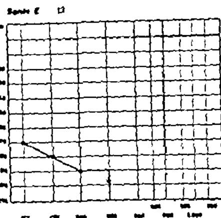

Fig. 22 (Sauro E., aged 13.) Patient with gravely diminished I.Q. through severe neonatal jaundice from materno-foetal incompatibility of Rh system. Audiometric examination by free-field C.O.R. study revealed severe auditory deficiency.

during first 6 months of life. Severe alteration in trophism and motoricity. Walking began at about 6 years of age.

The objective neurological examination revealed divergent strabismus. The upper limbs, especially the right, presented in flexion, and lower limbs in an attitude of slight adduction. Also bilateral Babinski. Walking spastic in type.

E.E.G. under barbiturate sleep: no signs with clear pathological significance noted.

I.Q. undefinable.

Audiometric investigations: on 14.1.64 an examination was attempted with the usual toys for studying I.C.R. The patient displayed absolute resistance to any form of co-operation. He not only wouldn't push the button but even refused to look at the toys. The test was suspended after several tries because he kept his face hidden on his mother's shoulder. After about an hour had elapsed, an attempt was made to perform an examination through C.O.R. study.

During this investigation the patient remained permanently in an attitude of opposition, with face hidden on his mother's shoulder. But when grave tones, 125 to 500 c/s at 90–100 dB, were routed into the speaker, he raised his head slightly and tried to look at the colour projections over his mother's shoulder. If the examiner watched him, however, he quickly hid his face and shut his eyes.

The audiometric tests via C.O.R. study were repeated on 18.1.64. The patient, though remaining on the defensive, looked at the film when tones from 125 to 500 c/s were routed. The existence of moderate hearing residue was thereby established in correspondence with these frequencies (Fig. 22).

Present behaviour: patient is considered irrecoverable.

Fig 23 (A–F). Audiometric examination by I C R. study of a patient with spastic manifestations. The assistant first helped him to depress the push button causing colour transparencies to appear Then, though with some uncertainty he managed to understand what movements were necessary and was able to do them by himself showing interest in the game linked with the examination.

(c) *Spastic or athetosic subjects*

Audiometric investigations into these patients may present difficulties chiefly because owing to altered functionality of certain muscular groups they are unable to execute or co-ordinate the reflex movements telling the examiner that the sound stimulus has been perceived

In *spastic subjects* with slight or moderate clinical manifestations the audiometric examination can be performed by helping the child to do the movements he should make when he hears the auditory signal

Let us take as an example the case where the investigation is done by way of I C R study the subject can be helped to push the button setting the toy in motion, provided that he hints at wanting to do so (Fig. 23)

In severer cases it will be enough to receive

even a small sign of the child's intention, and the examiner can push the button.

In *subjects with athetosic manifestations* the examination is generally very much more painstaking. As is known, movements are accentuated in these patients and they are exacerbated in all emotive situations, especially when they are required to accomplish motor actions of some precision. The considerable difficulties entailed in audiometric examination under such conditions are consequently understandable. Even with C.O.R. study the results will depend upon the gravity of spontaneous movements of the cephalic extreme. When the subject's head continually accomplishes in-co-ordinated movements, in fact, it is impossible to determine whether an orientation reflex of the head appears or not.

But at times when the tone stimulus is routed, more-accentuated athetosic movements or a series of grimaces may be had, or a smile in expectation of the reward, or a deviation of the eyeballs, reactions revealing that the stimulus has been perceived.

To be remembered, lastly, is that in cases where the patient can be given an instruction—that is, when it can be explained to him what movements he must do in the event of hearing a sound stimulus—an attempt can be made to get him to do any movement, even putting his tongue out (Finck & Finck) after each perceived tone emission.

We consider anyway that, except in cases with spastic manifestations of moderate entity it is difficult to subject these patients to consulting-room examination using objective audiometry.

It will often be necessary to have them admitted to specialized centres where they can undergo repeated investigation and prolonged observation. It will thereby be possible to gather all the information useful to any training.

Iadevaro R. Age 6 years. Born at term. Weight 3.35 kg.

Very severe jaundice few hours after birth, from materno-foetal incompatibility of the Rh system. Total exchange transfusion.

Neurological findings: subject presented grave difficulty in feeding during first three months of life. Severe neonatal hypotonia. Walking began towards 18th month. Choreo-athetosic movements, especially of the neck and upper limbs, as well as oculogyric crises, were noted at 3 years of age. At 4 walking was still uncertain, with a drunken gait.

As to phonation, he uttered no word although his mother stated he was able to understand various phonemes if scanned in loud voice.

E.E.G. subcortical abnormalities with irritative features.

I.Q. established by non-verbal tests is 0.87–0.90.

Audiometric investigations: the first researches were conducted at the age of 4. They were made difficult by the patient's extreme instability and the motor in-co-ordination he displayed.

It was managed at times to make him understand the problems linked with I.C.R. audiometry but he assigned scant value within his perceptive range to the auditory stimulation, even when very intense, and thus did not properly execute the movements for informing the examiner as to perception of the sound. Moreover, when it was succeeded in disinhibiting him, he began to overturn objects and want the toys without submitting to any test.

He showed readiness to tire in the course of investigations based on C.O.R. study.

Because of all this it was impossible either to perform an examination or to collect indicative data as to his hearing abilities.

He was nevertheless admitted to a school for the hard-of-hearing. His adaptation during the first year was especially difficult. Indeed, he paid no attention to anything, took what he wanted, satisfied his bodily needs in the midst of his companions, in the classroom without warning the teacher. This was not due to his being unable to communicate with the teacher but utter indifference as to his environment and total disinhibition.

Slowly over the space of about 2 years, there was some improvement in both behaviour and motoricity. The training exercises could thus be started.

A fresh audiometric examination revealed a hearing loss of moderate entity on the conversation voice frequency (Fig. 24).

Present behaviour: in view of the audiometric findings it was decided to fit a hearing aid. It has thus been possible to improve the patient's phonatory training.

Athos P. Age 4 years. Twin birth. Weight 2.9 kg. The twin died at 1 month.

Severe jaundice a few hours after birth, lasting 20 days.

Neurological findings: during the neonatal period there were frequent temperature rises with convulsive events. Skeletal muscle tonicity appeared to be severely diminished as from the early months; upright position was achieved at around 16 months and walking began towards the 30th month. A state of general hyperreflexia was revealed during a control examination performed at the age of 4, swallowing of saliva appeared difficult and incomplete.

Fig 23 (A–F). Audiometric examination by I C R. study of a patient with spastic manifestations. The assistant first helped him to depress the push-button causing colour transparencies to appear Then, though with some uncertainty he managed to understand what movements were necessary and was able to do them by himself showing interest in the game linked with the examination.

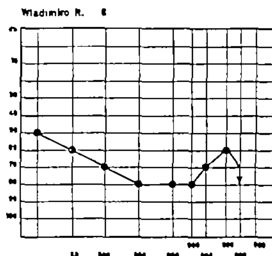

Fig 24 (*Vladimiro R* aged 6.) Subject with choreo-athetosic manifestations. Audiometric examination by I.C.R. study via earphone reveals a severe bilateral all-tone hearing loss.

E.E.G severe signs of deep distress.

I.Q and behaviour child docile and tranquil on the whole He watches what goes on around him but takes no part in his brothers games, confining himself to knocking down their toys or buildings. He is not aggressive he is almost indifferent to sounds or noises An attempt to perform the Borel Maisonny test met with complete failure.

Speech is practically non-existent

Audiometric investigation. examination only practicable through C O R. study Patient's responses uncertain and inconsistent, and merely enable one to suppose that severe deafness exists (Fig. 25)

Present behaviour owing to the considerable hearing disability and grave psycho-intellectual deficiency the patient has been sent to a centre for the multi handicapped

(d) Subjects multi-handicapped through foetal virosis contracted by mother during early months of intrauterine life

We think it important to discuss our observations in some subjects who as a result of rubeolar infection suffered by the mother during the early months of pregnancy presented, besides a usually very severe disability in hearing, a defect either in visual function or intelligence and at times also altered structuring of symbolic functions Performing the audiometric examination clearly presents considerable difficulties Consequently the audiologist drawing upon his own experience must know how to select the most suited technique from those we have described But there is no doubt that not infrequently the problems linked with audiometric examination are complicated due mainly to the scant co-operation patients are able to give in view of their psycho-intellectual handicaps. Moreover their visual defects often do not allow instrumental and orientation conditioned reflexes to be studied. The examiner thereby finds himself deprived of the techniques which, as we have illustrated, can provide the best results within the field of infant audiology

But there is no doubt that if he exercises particular patience in the research he can detect specific reactions by the patient as a result of the various stimulations, that will allow him to obtain an audiogram which if not accurate, is at least indicative

Indeed even when the patient cannot see the toys properly owing to ocular lesions, he can nevertheless present the conditioned reflex reactions either because he vaguely distinguishes the movements of the toys, or is able to perceive the light stimuli (To be recalled in this connection is that on both sides of the show for C O.R. study there are always intense light sources consisting either of the lamp illuminating the doll recess or independent lamps of different colours—cf page 31)

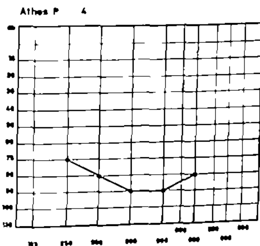

Fig 25 (*Athos P* aged 4) Subject with spastic manifestations. Audiometric examination by free-field C O R. study discloses a severe bilateral hearing loss.

CONTENTS

1 Introduction

Most of our knowledge about the hydromechanical action of the inner ear we owe to the admirable work of Georg von Békésy (1960 *a*). His direct observations of the basilar membrane vibration established the travelling wave pattern of disturbance as the mode of response by which the cochlea reacts to sound. Upon tonal stimulation of the inner ear a travelling wave appears on the cochlear partition whose wavelength becomes shorter as we proceed from base to apex. The envelope of the displacement wave has a flat basal and a steeper apical slope this gives the envelope its typical asymmetrical shape. The position of the rather flat envelope maximum depends on stimulus frequency it shifts with decreasing frequency progressively from the basal towards the apical end of the cochlea. Observing the excursion of points along the membrane as a function of frequency von Békésy obtained their frequency response curves. When expressed in db per octave the typical slope values of his response curves are 6 db per octave for the low frequency and 20 db per octave for the high frequency branch

Von Békésy used in his studies stimulus frequencies of not more than 4 kHz, i.e. he worked in the apical, low frequency region of the basilar membrane. Recently the Mossbauer effect was put to use in studies of cochlear mechanics at the basal, high frequency end of the basilar membrane. Johnstone & Boyle (1967) and Johnstone (1969) working on the guinea pig obtained response curves with low frequency slope values of 12 db per octave and high frequency slope values of 70 to 100 db per octave at an SPL around 90 db. Rhode & Geisler (1969) measured in the squirrel monkey slope values of 5 to 10 db per octave on the low frequency side and 90 to 150 db per octave on the high frequency side.

It would seem that these more recent mechanical data conform better to the threshold-frequency response curves of primary auditory nerve fibres obtained by Tasaki (1954 1960) than do the curves of von Békésy However evidence compiled over the past few years on the discharge patterns of primary fibres makes it appear doubtful whether a simple relationship exists between the neural output from segments along the basilar membrane and the corresponding local mechanical input. Ingeniously devised experiments on the neural response to aperiodic stimuli (Kiang, 1965 de Boer 1969 Møller 1970) revealed a transducer mechanism with much less damping than is implied by the strongly damped response of the basilar membrane (Weiss, 1964 Flanagan, 1960 Siebert, 1962). Additionally threshold frequency response curves (tuning curves) obtained by several investigators (Katsuki et al., 1958 Kiang, 1965 Evans, 1970 *a*) are relatively narrow over a considerable part of the dynamic range and fibres respond to a wide band of frequencies only at relatively high sound pressures. In view of this discrepancy between the neural output data and the mechanical input data of the cochlear transducer as far as frequency selectivity is concerned it seems necessary to postulate a 'sharpening mechanism intervening between the mechanical displacement of the membrane and the resulting neural discharges in auditory nerve fibres. However at present mechanical data are only available for stimulus intensities of 90 db SPL or above, i.e. from that part of the dynamic range where neural tuning curves are wide. Thus there is the important question whether

output at x and H that at x_2. H and H_2 are represented as spatial impulses. Each hair-cell generator establishes a potential field according to the conductive properties of inner ear tissues and fluids. The decay of potential strength with longitudinal distance from the generating source is indicated for scala tympani by an exponential attenuation function. It can be clearly seen from the illustration that an electrode at point x_e records a potential which is the sum, or superposition of the contributions from the generators at x_1 and x_2. In the case of n hair-cell generators we obtain as expression for the electrical output at x_e.

$$CM(x_e) = \sum_{i=1} H(x_i)\,w(x_e - x_i)$$

$w(x_e - x_i)$ is a weighting factor which takes account of the signal attenuation between the point of generation x_i and the recording site x_e. We may conceive of the basilar membrane as infinitely densely packed with hair-cell operators and consequently arrive at an integral expression for the CM at x_e.

$$CM(x_e) = \int_{-\infty}^{\infty} H(x)\,W(x - x)\,dx \qquad (1)$$

Equation (1) is fundamental to the present study. It defines the relationship between the hair-cell output pattern along the basilar membrane, $H(x)$, and the resulting CM distribution along the cochlear scalae, $CM(x_e)$. $W(x - x)$ is a weighting function which brings into play the signal attenuation effective between the points x and x_e. The expression in equation (1) is a convolution integral and by analogy to linear communication theory we may call the connection between $H(x)$ and $CM(x_e)$ a 'spatial filter operation'. Hence $H(x)$ is the 'input function' and $CM(x_e)$ the corresponding output function. $W(x)$ is the spatial impulse response of the system.

Experiments to be described here were designed to examine the validity of equation (1). A suitable starting point seemed to be the study of CM distributions in response to high frequency tones. Such stimuli cause disturbances only in the basal coil of the cochlea and it seemed possible to measure very accurately and completely the corresponding CM patterns with a multi-electrode array arranged along the basal cochlea. At high frequencies the travelling waves have very short wavelengths and thus closely neighbouring hair cells are driven out of phase. One might expect therefore that phase cancellation is much more pronounced and that the spatial filter effect can be seen much better at high frequencies than at low ones.

it is permissible to simply extrapolate mechanical data to sound pressures lower than 90 db SPL where the neural response is extremely sharply tuned

Since the study by Tasaki Davis & Legouix (1952) it is well known that the excitation pattern along the basilar membrane may be investigated in an alternative way to that followed by von Békésy These authors inserted four pairs of differential electrodes into the four turns of the guinea pig s cochlea and they measured the longitudinal distribution of the cochlear microphonic (CM) in response to sinusoidal stimuli The resulting CM distributions and their dependence on stimulus frequency were qualitatively similar to von Békésy s observations on the vibratory pattern of the basilar membrane. Legouix (1965/6 1969) using the same technique, studied the CM in response to impulsive stimuli His findings are in good qualitative agreement with mechanical data the transient CM response shows the typical strongly damped oscillations with a natural frequency characteristic to the region of the basilar membrane from which an electrode is recording There is good evidence that the CM response is associated with the shearing motion at the hair bearing end of the sensory hair cells (von Békésy 1960 *a*) and that it originates in the region of the receptor pole of the hair cells (Tasaki et al 1954) That is why we shall use throughout this study the term hair-cell generator when strictly speaking we only mean the source of the CM in the organ of Corti

Thus there are basically two ways in which the excitation pattern along the basilar membrane may be studied In the one mechanical excursions are measured directly In the other measurement is made of the electrical potentials which are the consequence of the mechanical excursions The greater sensitivity inherent in the electrical method offers the advantage that the CM can be used to explore the excitation pattern in the region of lower sound pressures, i.e in the region below 90 db where the minute membrane deflections have

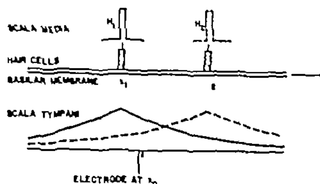

Fig 1 1 Diagram to show the interference of hair-cell outputs (*H* and *H*) in the cochlear fluids due to signal spread along the canals. Electrode at x_0 records a potential which is the sum of the attenuated contributions from hair-cell generators at *x* and *x*

not yet been resolved by mechanical methods. The disadvantage of the electrical method, however is one of data interpretation in the past there has been considerable uncertainty on the question how to evaluate exactly CM recordings taken with electrodes from the cochlear fluids. This question concerns the relationship between the potentials generated within the organ of Corti and those picked up by recording electrodes. A constructive step towards a better understanding was taken by Whitfield & Ross (1965) in a theoretical study They defined mathematically the relationship between hair-cell generator potentials and electrode outputs. According to this definition an electrode records the 'weighted sum of the electrical activity along the membrane This, it is argued is due to the fact that hair-cell potentials spread out and interfere with each other to a considerable extent in the inner ear fluids. Thus the spatial spread of signals in the cochlea was recognised to be instrumental to the quantitative interpretation of CM data and a reappraisal of CM measurements seemed appropriate

The present investigation developed logically from the mathematical formula relating hair cell output to electrode output In Fig 1 1 two hair-cell generators are schematically shown situated on the basilar membrane at points *x* and x_2 respectively Let *H* be the electrical

output at x_1 and H_2 that at x_2. H_1 and H_2 are represented as spatial impulses. Each hair-cell generator establishes a potential field according to the conductive properties of inner ear tissues and fluids. The decay of potential strength with longitudinal distance from the generating source is indicated for scala tympani by an exponential attenuation function. It can be clearly seen from the illustration that an electrode at point x_e records a potential which is the sum, or superposition of the contributions from the generators at x_1 and x_2. In the case of n hair-cell generators we obtain as expression for the electrical output at x_e.

$$CM(x_e) = \sum_i H_i(x_i)\, w(x_e - x_i)$$

$w(x_e - x_i)$ is a weighting factor which takes account of the signal attenuation between the point of generation x_i and the recording site x_e. We may conceive of the basilar membrane as infinitely densely packed with hair-cell operators and consequently arrive at an integral expression for the CM at x_e.

$$CM(x_e) = \int_{-\infty}^{\infty} H(x)\, W(x_e - x)\, dx \qquad (1)$$

Equation (1) is fundamental to the present study. It defines the relationship between the hair-cell output pattern along the basilar membrane, $H(x)$, and the resulting CM distribution along the cochlear scalae, $CM(x_e)$. $W(x_e - x)$ is a weighting function which brings into play the signal attenuation effective between the points x and x_e. The expression in equation (1) is a convolution integral and by analogy to linear communication theory we may call the connection between $H(x)$ and $CM(x_e)$ a 'spatial filter operation'. Hence $H(x)$ is the input function and $CM(x_e)$ the corresponding output function. $W(x)$ is the spatial impulse response of the system.

Experiments to be described here were designed to examine the validity of equation (1). A suitable starting point seemed to be the study of CM distributions in response to high frequency tones. Such stimuli cause disturbances only in the basal coil of the cochlea and it seemed possible to measure very accurately and completely the corresponding CM patterns with a multi-electrode array arranged along the basal cochlea. At high frequencies the travelling waves have very short wavelengths and thus closely neighbouring hair cells are driven out of phase. One might expect therefore that phase cancellation is much more pronounced and that the spatial filter effect can be seen much better at high frequencies than at low ones.

2 Methods

For the study of the spatial filter effect it was necessary to obtain a detailed picture of the CM distribution over a sufficient length of the cochlea. Analysis of the microstructure of CM patterns with equation (1) seemed only a promising enterprise provided accurate and reliable data about the longitudinal course of the CM were made available. The accommodation of an assembly of closely spaced electrodes allowing the detailed inspection of CM patterns was the central problem in the development of suitable techniques.

The set of recording electrodes was placed in the basal scala tympani of the guinea pig's cochlea. This site was chosen for mainly two reasons. First this part of the cochlea appeared to be spacious enough to allow the insertion of several electrodes without damage to the cochlear partition. Second the CM response to high frequency stimuli was expected to show the spatial filter effect most clearly. It was therefore imperative to execute measurements in the basal area where the response to such stimuli is known to occur.

The choice of the basal cochlea as recording site carried the advantage that the conditions of current spread have been studied most extensively for this part of the cochlear ducts (see Section 3 Weighting Function). As to the question which recording technique should be used, the differential technique with a set of paired electrodes along the cochlear partition or the simpler technique with a set of electrodes in one scala and a common reference electrode outside the cochlea, e.g. on the animal neck, there seemed to be no objection from existing evidence to using the simpler technique. For CM recordings from the upper turns of the guinea pig's cochlea most workers have preferred the differential technique, i.e. they recorded the potential difference between one electrode in scala tympani and one opposite in scala vestibuli. It has been suggested in the literature (Tasaki et al. 1952; Tasaki & Fernández, 1952) that the differential technique is superior to the alternative of measuring potentials between one electrode in scala tympani and the other on the neck. A differential pair of electrodes is supposed to record potentials only from one turn without contamination by signals arising from neighbouring turns. However Tasaki & Fernández felt that for the basal coil such a superiority did not exist and they stated: The microphonic recorded with one electrode on the neck and the other in the basal turn, either in scala vestibuli or in scala tympani, gives information as to the activity taking place in the basal turn without contamination by the responses originating in the upper turns. Recently Dallos (1969 *a*) confirmed this statement in a thorough study. Apart from the fact that the differential technique recorded potentials larger by 6 db in the basal turn he could not find any advantage over the simpler technique, i.e. one electrode in the basal scala tympani and the reference on the neck. In our case the simpler technique is preferable for mainly two reasons: 1) The technical difficulties in setting up a differential recording situation with twelve closely spaced pairs of electrodes are most probably prohibitive. 2) Cross-conduction between scala vestibuli and scala tympani via the fluid leaking out of the openings in the cochlear wall would probably be unavoidable. This would introduce uncontrollable current loops short-circuiting the cochlear partition. Thus it is clear that the disadvantages of the differential technique in

our case, outweigh the advantage of recording potentials larger by 6 db.

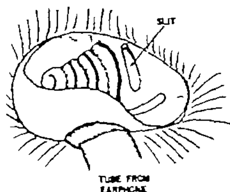
The problem of arranging a set of recording electrodes over a short length of the basilar membrane seemed to be most elegantly tackled by the use of a multi-electrode probe manufactured with the modern techniques of microminiaturization. Such a probe was manufactured for this project in the Lucas Research Department, Shirley Birmingham. Twelve narrow stripes of aluminium were photoetched onto a glass substrate which was cut into a rectangular shape appropriate for the insertion of the probe through a slit into scala tympani. However this approach proved unsuccessful because the probe was brittle and much too delicate to be repeatedly used in a large series of experiments. Thus very early on, during the exploratory phase of the project, the probe broke and this technique was discontinued. After this failure an alternative technique was adopted. A series of up to twelve holes was drilled into the wall of the basal scala tympani parallel to the basilar membrane and stainless steel wire electrodes were inserted into the holes. The placement of electrodes was extremely time-consuming. This method was finally abandoned in favour of the ultimate optimum technique which allowed the rapid collection of data. A multi-electrode array was constructed by gluing insulated stainless steel wires together. The elastic, ribbon-like array thus formed could be easily inserted through a slit into scala tympani alongside the basilar membrane.

SURGICAL PROCEDURE

All guinea pigs were anaesthetised with Urethane administered intraperitoneally at a dose of 1.25 g kg. Tracheotomy was performed and a short polythene cannula was inserted into the trachea. The bulla on the animal's right side was exposed in the standard latero-ventral fashion described by Tasaki & Fernández (1952). Then the animal was mounted in a stereotaxic instrument with the head rigidly clamped between the skull and the upper jaw bone in a head holder. The external auditory meatus was exposed and cut across leaving only a short 'sleeve' for the insertion of the coupling tube of the earphone.

With a number of wire hooks the tissue surrounding the bulla was carefully retracted. The bulla was opened with a dental drill and part of the bony shell was removed with a forceps. Thereafter the cochlea protruding into the middle ear cavity was conveniently accessible for surgical manipulation. With small pieces of cotton wool the surface of the cochlea was cleaned and dried.

After these preliminary operations microdissection began with the aid of a Zeiss otoscope which both illuminated and magnified the operative field. With a small, round dental burr (1/4 C. Ash & Sons) the wall of the basal 1/2 turn of scala tympani was thinned down to uniform thickness along the course of the basilar membrane. The thickness was reduced until the bony wall was almost transparent. This procedure had to be executed with utmost care. Accidental sideways slipping of the burr by only about 1 mm and subsequent injury to the retracted tissue in the immediate vicinity could cause bleeding and filling of the middle ear cavity with blood. Removal of blood clots especially from the stapedial region was very delicate. It was found empirically that guinea pigs weighing about 500 g possessed cochlear walls with the optimum mechanical consistency for this operation. Guinea pigs below this weight had cochleae too fragile and heavier animals usually had a bony shell too hard and brittle. In either extreme case it could easily happen that the cochlear shell broke during the drilling process.



In the early experiments ('single electrode technique') a number of holes were drilled with a stiff needle into the wall of scala tympani parallel to the basilar membrane. Since it was desirable to accomplish a fairly regular spacing of the holes the needle was mounted in a heavy handle. The weight of the handle stabilized the needle once it was placed on the

2 Methods

For the study of the spatial filter effect it was necessary to obtain a detailed picture of the CM distribution over a sufficient length of the cochlea. Analysis of the microstructure of CM patterns with equation (1) seemed only a promising enterprise provided accurate and reliable data about the longitudinal course of the CM were made available The accommodation of an assembly of closely spaced electrodes allowing the detailed inspection of CM patterns was the central problem in the development of suitable techniques.

The set of recording electrodes was placed in the basal scala tympani of the guinea pig s cochlea. This site was chosen for mainly two reasons. First this part of the cochlea appeared to be spacious enough to allow the insertion of several electrodes without damage to the cochlear partition. Second the CM response to high frequency stimuli was expected to show the spatial filter effect most clearly It was therefore imperative to execute measurements in the basal area where the response to such stimuli is known to occur

The choice of the basal cochlea as recording site carried the advantage that the conditions of current spread have been studied most extensively for this part of the cochlear ducts (see Section 3 Weighting Function) As to the question which recording technique should be used, the differential technique with a set of paired electrodes along the cochlear partition or the simpler technique with a set of electrodes in one scala and a common reference electrode outside the cochlea e g on the animal neck, there seemed to be no objection from existing evidence to using the simpler technique. For CM recordings from the upper turns of the guinea pig s cochlea most workers have preferred the differential technique i e they recorded the potential difference between one electrode in scala tympani and one opposite in scala vestibuli It has been suggested in the literature (Tasaki et al 1952 Tasaki & Fernández, 1952) that the differential technique is superior to the alternative of measuring potentials between one electrode in scala tympani and the other on the neck A differential pair of electrodes is supposed to record potentials only from one turn without contamination by signals arising from neighbouring turns. However Tasaki & Fernández felt that for the basal coil such a superiority did not exist and they stated 'The microphonic recorded with one electrode on the neck and the other in the basal turn either in scala vestibuli or in scala tympani gives information as to the activity taking place in the basal turn without contamination by the responses originating in the upper turns Recently Dallos (1969 a) confirmed this statement in a thorough study Apart from the fact that the differential technique recorded potentials larger by 6 db in the basal turn he could not find any advantage over the simpler technique i e one electrode in the basal scala tympani and the reference on the neck In our case the simpler technique is preferable for mainly two reasons 1) The technical difficulties in setting up a differential recording situation with twelve closely spaced pairs of electrodes are most probably prohibitive 2) Cross-conduction between scala vestibuli and scala tympani via the fluid leaking out of the openings in the cochlear wall would probably be unavoidable This would introduce uncontrollable current loops short-circuiting the cochlear partition Thus it is clear that the disadvantages of the differential technique in

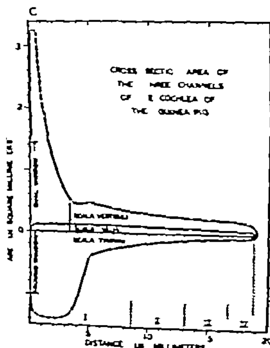


Fig. 2.1 (A) Schematic drawing of the exposed right cochlea of the guinea pig. The slit in the wall of the basal 1 2 turn of scala tympani is shown. (It is in the experiments approximately 2 mm long and 0.5 mm wide.) The slit runs parallel to the basilar membrane. The position of the stria vascularis is marked as dark band.

(B) Right cochlea of the guinea pig with organ of Corti exposed. This photograph was taken from Engstrom et al (1966). The schematic representation of the electrode array tips was superimposed on the photograph in order to show the approximate array position relative to the basilar membrane.

(C) Cross section area of canals according to Fernandez (1952). The slit in the wall of scala tympani would—when plotted in this graph—extend from about 3 to 5 mm along the abscissa. The most basal electrode of the array 1 would be located between 3 to 3.5 mm

completely and there was no danger of further formation of blood clots. Finally the Ringer fluid was sucked out of the middle ear cavity without, however removing fluid from scala tympani.

Then with a micromanipulator arrangement the multi-electrode array was inserted through the slit into scala tympani to a depth of about 300 to 400 μ. The tips of the recording electrodes were thus located in a line running at a distance of about 500 μ parallel to the basilar membrane.

THE MULTI-ELECTRODE PROBE

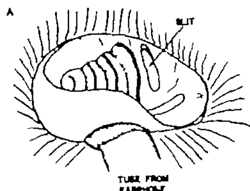
A. Manufacture of the array

The multi-electrode probe was the central piece of equipment for the measurement of

bony wall and prevented sideways slipping Up to twelve separate holes could be drilled in this way each with a diameter of about 70–100 μ Insulated 50 μ stainless steel wire electrodes were inserted into the holes. The insulation coating formed small blobs along the shaft of the electrodes and 400 μ away from a suitably shaped blob the electrodes were cut before insertion Thus each individual electrode was selected and matched to a particular hole the blob serving as depth control and as closure of the hole. The steel wires had just the right combination of flexibility and stiffness which was essential for the successful placement of a set of electrodes. Thus previous attempts with more flexible silver electrodes failed The steel electrodes were about 50 mm long and were soldered to slim cylindrically shaped handles made of brass. After an electrode was inserted into scala tympani the brass handle was pushed into a complementary brass cylinder arranged in a perspex block (see Fig. 2 6) The elastic force due to the bending of the electrode between the points of fixation—i e the hole in scala tympani and the perspex block—pressed the electrode slightly against the hole and thus held the electrode in a stable position This stabilization was extremely important since during the course of inserting electrodes it was impossible not to touch and disturb electrodes already in place it is only by virtue of the springiness of the steel wires that electrodes stayed in place despite disturbances. The minimum distance between the holes could not be reduced below 0 3 mm without breaking the bony ridges between holes With the need for more closely spaced electrodes the single electrode technique was abandoned in favour of the multi-electrode technique

In the latter technique a multi-electrode array was inserted into a slit like opening in the wall of scala tympani The slit was manufactured in one of two ways Drilling of a series of adjacent holes by means of a steel needle and subsequent breaking of the bony bridges between holes with a fine forceps was the one way As alternative to this indirect method there was the direct way of drilling the slit with a small round dental burr (1/4 C. Ash & Sons) Extreme care and an absolutely steady hand were prerequisite for the success of this procedure It was necessary to widen the slit so formed in both cases with a fine forceps. The shape of the slit was made to match the dimensions of the electrode array by cautiously breaking minute pieces of bone from the rims of the slit Care had to be taken not to approach too closely the region of the attachment of the basilar membrane to the wall of scala tympani. The slit had a length of about 2 mm and a width of about 0.5 mm It extended from about 3 to 5 mm along the basilar membrane measuring from the basal end of the membrane (see Fig 2.1 A B C)

Small blood vessels lining the floor of scala tympani opposite to the basilar membrane were usually injured during the formation of the slit As a consequence blood clots formed inside scala tympani and it was clear that these clots would seriously distort the pattern of electrical conductivity in the scala Attempts to remove the blood clots with a fine forceps were usually fatal because the sharp prongs of the forceps easily pierced the thin bony floor of scala tympani towards the modiolar core In these cases the CM recorded from the basal scala tympani had a very low amplitude and there was practically no longitudinal phase variation Obviously the accidental hole in the modiolar wall effectively earthed scala tympani via the VIII nerve (see von Békésy 1960 a p 660) In order to remove the blood clots from the duct another procedure was adopted The middle ear cavity was filled with mammalian Ringer solution so that the slit in scala tympani was well below the fluid level A syringe also filled with Ringer solution was held over the slit and the plunger of the syringe was slowly moved inwards and outwards. This produced streaming of fluid and effectively washed out the blood clots from scala tympani. This procedure was repeated several times until it was certain that bleeding had ceased



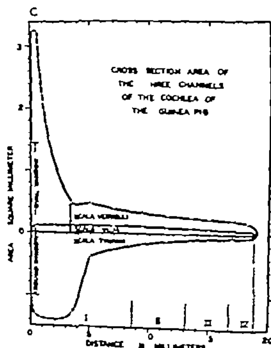


Fig. 2.1 (A) Schematic drawing of the exposed right cochlea of the guinea pig. The slit in the wall of the basal 1/2 turn of scala tympani is shown. THE MULTI-ELECTRODE PROBE

A. Manufacture of the array

The multi-electrode probe was the central piece of equipment for the measurement of

bony wall and prevented sideways slipping. Up to twelve separate holes could be drilled in this way each with a diameter of about 70–100 μ. Insulated 50 μ stainless steel wire electrodes were inserted into the holes. The insulation coating formed small blobs along the shaft of the electrodes and 400 μ away from a suitably shaped blob the electrodes were cut before insertion. Thus each individual electrode was selected and matched to a particular hole the blob serving as depth control and as closure of the hole. The steel wires had just the right combination of flexibility and stiffness which was essential for the successful placement of a set of electrodes. Thus previous attempts with more flexible silver electrodes failed. The steel electrodes were about 50 mm long and were soldered to slim cylindrically shaped handles made of brass. After an electrode was inserted into scala tympani the brass handle was pushed into a complementary brass cylinder arranged in a perspex block (see Fig. 2.6). The elastic force due to the bending of the electrode between the points of fixation—i.e. the hole in scala tympani and the perspex block—pressed the electrode slightly against the hole and thus held the electrode in a stable position. This stabilization was extremely important since during the course of inserting electrodes it was impossible not to touch and disturb electrodes already in place. It is only by virtue of the springiness of the steel wires that electrodes stayed in place despite disturbances. The minimum distance between the holes could not be reduced below 0.3 mm without breaking the bony ridges between holes. With the need for more closely spaced electrodes the single electrode technique was abandoned in favour of the multi-electrode technique.

In the latter technique a multi-electrode array was inserted into a slit-like opening in the wall of scala tympani. The slit was manufactured in one of two ways. Drilling of a series of adjacent holes by means of a steel needle and subsequent breaking of the bony bridges between holes with a fine forceps was the one way. As alternative to this indirect method there was the direct way of drilling the slit with a small round dental burr (1/4 C. Ash & Sons). Extreme care and an absolutely steady hand were prerequisite for the success of this procedure. It was necessary to widen the slit so formed in both cases with a fine forceps. The shape of the slit was made to match the dimensions of the electrode array by cautiously breaking minute pieces of bone from the rims of the slit. Care had to be taken not to approach too closely the region of the attachment of the basilar membrane to the wall of scala tympani. The slit had a length of about 2 mm and a width of about 0.5 mm. It extended from about 3 to 5 mm along the basilar membrane measuring from the basal end of the membrane (see Fig. 2.1 A, B, C).

Small blood vessels lining the floor of scala tympani opposite to the basilar membrane were usually injured during the formation of the slit. As a consequence blood clots formed inside scala tympani and it was clear that these clots would seriously distort the pattern of electrical conductivity in the scala. Attempts to remove the blood clots with a fine forceps were usually fatal because the sharp prongs of the forceps easily pierced the thin bony floor of scala tympani towards the modiolar core. In these cases the CM recorded from the basal scala tympani had a very low amplitude and there was practically no longitudinal phase variation. Obviously the accidental hole in the modiolar wall effectively earthed scala tympani via the VIII nerve (see von Békésy 1960 *a* p. 660). In order to remove the blood clots from the duct another procedure was adopted. The middle ear cavity was filled with mammalian Ringer solution so that the slit in scala tympani was well below the fluid level. A syringe also filled with Ringer solution, was held over the slit and the plunger of the syringe was slowly moved inwards and outwards. This produced streaming of fluid and effectively washed out the blood clots from scala tympani. This procedure was repeated several times until it was certain that bleeding had ceased.

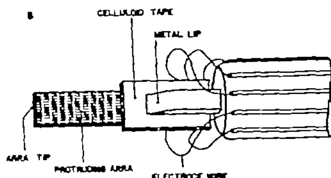

Fig 2.3 (A) Photograph of the electrode probe carrier' (scale division in mm).

(B) Schematic drawing of the tip of the electrode probe carrier' with the electrode *array mounted*.

carrier and the main shaft. It contained the electrical components necessary for the a.c. coupling between electrodes and preamplifiers. (For the measurement of cochlear d.c.-potentials this a.c.-coupler could be removed. In the experiments reported here no d.c.-measurements were undertaken and the a.c.-coupler was always in place.)

The shape of the complete electrode array holding unit represented a compromise between two partly conflicting design criteria. It was desirable to make the twelve wires leading away from the recording site as short as possible in order to minimize capacitive cross-talk, i.e. the preamplifiers had to be as close as possible to the recording site. On the other hand the preamplifiers had to be accommodated at a sufficient distance from the operative field not to obstruct the experimenter's vision.

C. Insertion of the electrode array into scala tympani

The alignment of wires was checked under the Zeiss otoscope before insertion of the tip of the electrode array into scala tympani. During the course of three to four experiments usually small pieces of polystyrene broke away from the tip of the array causing an irregular spacing of electrode terminals. By carefully cutting the tip of the array with a pair of scissors it was possible to use the remaining intact part of the array for further experiments. In this way the same array could be used for about ten successive experiments.

For the placement of the array in scala

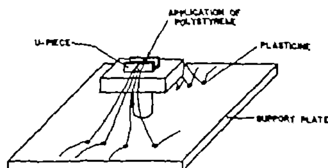

Fig 2.2 Schematic drawing of the wire assembly arrangement.

the longitudinal distribution of the CM response. The individual electrodes composing the probe were made of the same 50 μ stainless steel wire which was used in the single electrode technique. Steel wires, about 150 mm long, were slowly drawn through a bath of Bakelite Insulating Lacquer The coat so formed was then baked for not less than 20 min in an oven at 180 C. Wires were given at least three coats.

Twelve insulated wires were assembled side by side in a single plane and they were bonded together with polystyrene The assemblage was carried out under visual control (Zeiss otoscope) In order to achieve an accurate alignment of the electrodes in a single plane the wires were pulled over the edges of a U shaped piece of metal. A schematic drawing of the simple assembly arrangement is given in Fig 2.2. The procedure began by tightly pulling the first insulated wire over the U piece and fixing the wire ends on the support plate with plasticine The second wire was arranged in the same way close to the first one With a paint brush a small droplet of a polystyrene benzene solution was spread along the electrode wires over a length of about 15 mm Due to the surface tension of the liquid the wires were pulled close together The polystyrene dried rapidly and fixed the wires Then the third electrode was bonded to the second one and the manipulation was repeated until all twelve electrode wires were glued together In the event that any particular wire within the set was not aligned properly a small drop of benzene was applied so that the polystyrene softened locally This made a realignment of the wire possible

The distance between adjacent electrode wires was mainly determined by the blob-like thickenings of the insulation coating along the wires. It was possible to achieve a regular spacing of electrode wires in the array by carefully selecting wires with approximately equal blob sizes. Thus the distance between the centres of adjacent electrodes varied from *about 150 to 180 μ Since the electrode dia*meter was 50 μ this variation in distance was considered tolerable.

B. Mounting of the electrode array

One end of the assembly of wires was trimmed with scissors and the completed ribbon like array was then mounted on the electrode probe carrier' (see Fig 2.3 A) A rectangular piece of ordinary film tape was glued to the small metal lip sticking out of the carrier shaft The electrode array was bonded with Eastman adhesive 910 to this flexible tape support in such a way that about 8 mm of the ribbon like array protruded beyond the support A schematic drawing of this arrangement is given in Fig. 2.3 B The free ends of the electrode wires were embedded with polystyrene in twelve grooves cut lengthwise into the round shaft of the carrier Finally after scraping off the insulation from the terminal section with a scalpel the electrode wires were soldered to twelve small steel bars permanently attached to the upper end of the carrier The carrier was made of heat resisting Teflon to avoid melting of carrier material during soldering

The carrier was then connected to the main part of the array holding unit (see Fig 2.4) This part consisted of a round perspex shaft with twelve permanently embedded steel wires leading to twelve preamplifiers arranged at the top end of the shaft A short cylindrical piece of perspex was inserted between the probe

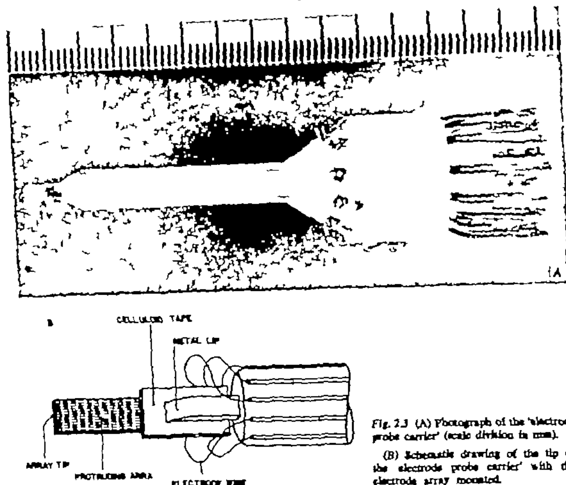

Fig. 2.3 (A) Photograph of the 'electrode probe carrier' (scale division in mm).

(B) Schematic drawing of the tip of the electrode probe carrier' with the electrode array mounted.

carrier and the main shaft. It contained the electrical components necessary for the a.c. coupling between electrodes and preamplifiers. (For the measurement of cochlear d.c.-potentials this a.c.-coupler could be removed. In the experiments reported here no d.c.-measurements were undertaken and the a.c.-coupler was always in place.)

The shape of the complete electrode array holding unit represented a compromise between two partly conflicting design criteria. It was desirable to make the twelve wires leading away from the recording site as short as possible in order to minimize capacitive cross-talk, i.e. the preamplifiers had to be as close as possible to the recording site. On the other hand the preamplifiers had to be accommodated at a sufficient distance from the operative field not to obstruct the experimenter's vision.

C. Insertion of the electrode array into scala tympani

The alignment of wires was checked under the Zeiss otoscope before insertion of the tip of the electrode array into scala tympani. During the course of three to four experiments usually small pieces of polystyrene broke away from the tip of the array causing an irregular spacing of electrode terminals. By carefully cutting the tip of the array with a pair of scissors it was possible to use the remaining intact part of the array for further experiments. In this way the same array could be used for about ten successive experiments.

the longitudinal distribution of the CM response. The individual electrodes composing the probe were made of the same 50 μ stainless steel wire which was used in the single electrode technique. Steel wires, about 150 mm long, were slowly drawn through a bath of Bakelite Insulating Lacquer The coat so formed was then baked for not less than 20 min in an oven at 180 C. Wires were given at least three coats.

Twelve insulated wires were assembled side by side in a single plane and they were bonded together with polystyrene. The assemblage was carried out under visual control (Zeiss otoscope) In order to achieve an accurate alignment of the electrodes in a single plane the wires were pulled over the edges of a U shaped piece of metal. A schematic drawing of the simple assembly arrangement is given in Fig 2.2. The procedure began by tightly pulling the first insulated wire over the U-piece and fixing the wire ends on the support plate with plasticine The second wire was arranged in the same way close to the first one. With a paint brush a small droplet of a polystyrene benzene solution was spread along the electrode wires over a length of about 15 mm Due to the surface tension of the liquid the wires were pulled close together The polystyrene dried rapidly and fixed the wires. Then the third electrode was bonded to the second one and the manipulation was repeated until all twelve electrode wires were glued together In the event that any particular wire within the set was not aligned properly a small drop of benzene was applied so that the polystyrene softened locally This made a realignment of the wire possible.

The distance between adjacent electrode wires was mainly determined by the blob-like thickenings of the insulation coating along the wires. It was possible to achieve a regular spacing of electrode wires in the array by carefully selecting wires with approximately equal blob sizes. Thus the distance between the centres of adjacent electrodes varied from about 150 to 180 μ Since the electrode diameter was 50 μ this variation in distance was considered tolerable.

B. Mounting of the electrode array

One end of the assembly of wires was trimmed with scissors and the completed ribbon like array was then mounted on the electrode probe carrier' (see Fig. 2.3 A) A rectangular piece of ordinary film tape was glued to the small metal lip sticking out of the carrier shaft. The electrode array was bonded with Eastman adhesive 910 to this flexible tape support in such a way that about 8 mm of the ribbon like array protruded beyond the support. A schematic drawing of this arrangement is given in Fig 2.3 B The free ends of the electrode wires were embedded with polystyrene in twelve grooves cut lengthwise into the round shaft of the carrier Finally after scraping off the insulation from the terminal section with a scalpel the electrode wires were soldered to twelve small steel bars permanently attached to the upper end of the carrier The carrier was made of heat resisting Teflon to avoid melting of carrier material during soldering

The carrier was then connected to the main part of the array holding unit (see Fig 2.4) This part consisted of a round perspex shaft with twelve permanently embedded steel wires leading to twelve preamplifiers arranged at the top end of the shaft. A short cylindrical piece of perspex was inserted between the probe

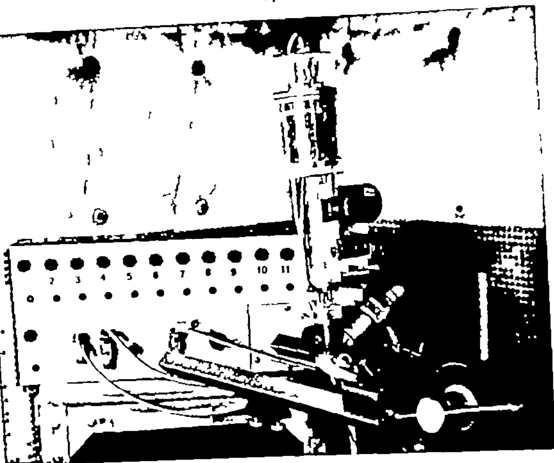

Fig. 2.5. Photograph showing the electrode array holding unit in the experimental position on the stereotaxic instrument. The array tip is inserted into the basal scala tympani of the right cochlea in the guinea pig skull. The holding unit is coupled via the ball joint to manipulator II. Preamplifiers on the holding unit are connected to the twelve main amplifiers contained in the box, shown in the background. The screened condenser earphone with the short metal tube for the acoustic coupling is displayed next to the guinea pig skull.

ELECTRICAL PROPERTIES OF THE ELECTRODE CHANNELS

It was essential for the faithful measurement of the CM distribution in the basal scala tympani that all data channels had identical electrical characteristics. In Fig. 2.7 one such channel is shown schematically representative for the whole set of the twelve parallel channels. The electrode wire was a.c.-coupled to the preamplifier. (Both a.c.-coupler and preamplifier were attached to the array holder.) The preamplifier was connected with a cable to the main amplifier stage contained in a separate box. The preamplifier in series with the main amplifier formed the "channel amplifier".

Recordings were taken between the sensing electrodes in scala tympani and an indifferent electrode on the animals neck. Hence the "internal impedance of the signal source was the sum of two components. The one component was the impedance between the basal scala tympani and animal earth which according to von Békésy (1960 *a*, p. 659) had a value of about 8 kΩ. The other component was the impedance at the electrode-perilymph interface. (The insulation coating was absent only at the cross section of the tip of the steel electrode.) This impedance amounted to ap-

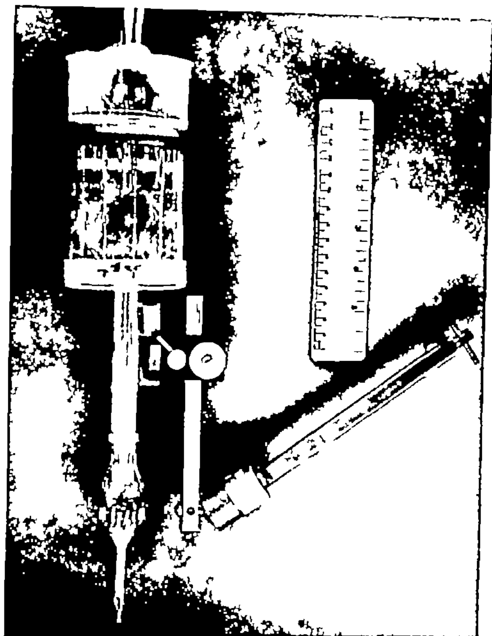

Fig 2 4 Photograph of the electrode array holding unit and preamplifiers. The small, ribbon-like electrode array is shown at the tip of the unit. The holding unit *is mounted on manipulator* I which in turn is coupled via the ball joint link (shown in the photograph) to manipulator II (shown *in* Fig. 2 5)

tympani a combination of two micromanipulators was employed (see Fig 2 4 and Fig 2.5) Manipulator I was coupled to manipulator II via a ball and-socket joint this gave sufficient freedom of movement to manoeuvre the *array tip into scala tympani through the narrow* slit in the cochlear wall The main shaft of the array holding unit was screwed to manipulator I With the ball joint unlocked manipulator I was tilted in such a way that the electrode array tip was in line with the slit in the basal turn Then the ball joint was locked and the electrode array position was adjusted in the lateral directions with manipulator II Finally the array was driven into scala tympani with manipulators I and II

D Channel connections in the 'single-electrode' technique

In the single-electrode technique all electrodes were mounted in a perspex block (see Fig. 2.6). *With short leads connection was made to* the a c.-coupler attached to the main shaft of the array holding unit. Thus in both techniques *the same channel amplifiers were employed for* the recording of potentials.

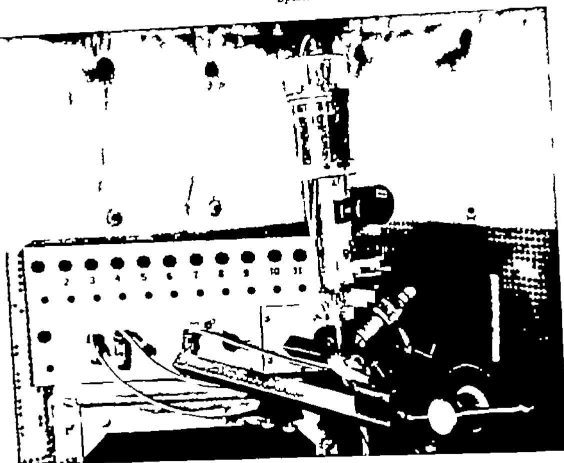

Fig 2.5. Photograph showing the electrode array holding unit in the experimental position on the stereotaxic instrument. The array tip is inserted into the basal scala tympani of the right cochlea in the guinea pig skull. The holding unit is coupled via the ball joint to manipulator II. Preamplifiers on the holding unit are connected to the twel e main amplifiers contained in the box, show in the background. The screened condenser earphone with the short metal tube for the acoustic coupling is displayed next to the guinea pig's skull.

ELECTRICAL PROPERTIES OF THE ELECTRODE CHANNELS

It was essential for the faithful measurement of the CM distribution in the basal scala tympani that all data channels had identical electrical characteristics. In Fig. 2.7 one such channel is shown schematically representative for the whole set of the twelve parallel channels. The electrode wire was a.c.-coupled to the preamplifier (Both a.c.-coupler and pre amplifier were attached to the array holder.) The preamplifier was connected with a cable to the main amplifier stage contained in a separate box. The preamplifier in series with the main amplifier formed the channel amplifier'

Recordings were taken between the sensing electrodes in scala tympani and an indifferent electrode on the animals neck. Hence the 'internal impedance of the signal source was the sum of two components. The one component was the impedance between the basal scala tympani and animal earth which according to von Békésy (1960 *a* p. 659) had a value of about 8 kΩ. proximately 30 kΩ. Due to the high input resistance of the preamplifiers (22 MΩ) there was no danger that slight differences in the "internal impedance" of the twelve channel sources would distort the measurement of the CM pattern. In addition the high input resistance of the preamplifiers served a further purpose. It was important not to introduce with the sensing equipment current loops of high conductivity which could alter the conductivity pattern present in the cochlea. The high input impedance of the data channels prevented such

a disturbance of the current distribution in scala tympani.

All twelve transistorized amplifiers were built identically and they had the same flat frequency response from 0 to 20 kHz. The 3 db cut-off frequency was 40 kHz. Since electrodes were a.c.-coupled to the amplifiers a lower 3 db cut-off frequency of about 10 Hz was introduced. Thus over the frequency range (500 Hz to 20 kHz) used in the study the frequency response of the amplifiers was flat. The gain factor of the channel amplifiers was set at 500. However, despite careful adjustment there remained a slight difference of maximally 2% between the gain factors of different channels.

A problem of major concern in the design and construction of electrode channels was the minimization of channel interaction. Only in the case of negligible interaction would channel outputs represent a replica of the original potential distribution in the cochlea. There were two potential sources of significant electrical interaction of the individual channels. First there was the interaction due to capacitive cross-talk. Its influence was kept at a minimum by making the wires from the recording site to the preamplifiers as short as possible and by screening the individual ampli-

fier channels. Second, since all channel amplifiers were fed from the same power supply there was a possibility of a channel interaction via the internal impedance of the power supply. This problem was solved by choosing a power supply unit with a small internal impedance.

Channel interaction was determined by inserting a test signal into one data channel and measuring the response in the idle adjacent channels. It turned out that the channel interaction could be considered negligible for our purposes. The response in the idle channels was maximally only about 1 to 1.5% of the response in the test channel and this was at the highest frequency employed in the study (20 kHz).

SOUND GENERATING EQUIPMENT

The stimulus signal was derived from two Solartron oscillators (Type CO 546) each of which was equipped with an attenuator covering a range of 60 db. The signal was fed via a 600Ω adaptor to the microphone amplifier. The latter was built in this laboratory. It had a flat frequency response from 100 Hz to 30 kHz and a gain factor of 29. Its linear dynamic range extended up to an output voltage of about 55 V rms. The output of the microphone amplifier was connected to the one-inch condenser microphone (Bruel & Kjaer 4132) which was used in the experiments as earphone, i.e. as electro-acoustic transducer. The voltage (190 V d.c.) for the polarization of the condenser microphone was supplied by the microphone amplifier.

The acoustic output of the one-inch condenser microphone was coupled via a short piece of metal tubing (length 15 mm) to the guinea pig's external ear. The transducer was carefully screened in order to prevent direct pick-up of the stimulus signal by the recording electrodes.

The calibration of the sound equipment was executed by monitoring the sound pressure in front of the eardrum with the aid of a calibrated sensing probe connected to a half-inch condenser microphone (Bruel & Kjaer 4134). The output of the sensing microphone was fed to a Bruel & Kjaer Microphone Amplifier Type 2604. It was found from this measurement that the sound generating system had a reasonably flat frequency response. Thus, there was an SPL at the eardrum of 90 ± 3 db from 200 Hz to 10 kHz for an oscillator output of 4 V rms and an attenuator setting of 25 db. The SPL had a value of 100 ± 5 db in the frequency range from 10 kHz to 20 kHz. (The standard reference level for the sound pressure is 0.0002 dynes per cm².)

The condenser microphone introduced quadratic distortion so that the second harmonic of the stimulus frequency appeared in the acoustic signal. However, this effect could be neglected in the present study since the second harmonic was smaller than the actual signal by 40 db at stimulus intensities usually employed (80 to 90 db SPL).

RECORDING

The block diagram of the recording system is shown in Fig. 2.8. The input, output and reference channels are marked differently for reasons of clarity.

The animal was placed in a shielded, soundproofed room. A sinusoidal stimulus from oscillator O_1 was applied to the guinea pig's ear by closing push-button switch S_1. (In two-tone interaction and overstimulation studies oscillator O_2 was used as well.) The resulting CM responses were amplified by the twelve a.c.-coupled channel amplifiers. By means of switch S_2 a particular output channel was selected. The output was then fed through a B & K amplifier and 1/3 octave filter (Bruel & Kjaer Microphone Amplifier Type 2604. Bruel & Kjaer Band-Pass Filter Type 1612). The unfiltered output could be directly displayed on a dual-beam oscilloscope (Tektronix Type 502 A) for inspection of the waveform of the CM.

For a given stimulus all twelve outputs were measured, one at a time. The amplitude of the

Fig 2.9 Example of computer print out. (The data are dra in Fig 3 1.A, see 14.5 kHz record). Key Row 1 Record 21 30 db (corresponds to 85 db SPL), 14.50 kHz. Column 1 electrode numbers 1 to 12, 2 sine (electrode output); 3 cosine (electrode output)' 4 CM amplitude in μV rms 5 $\log_{10}$ CM amplitude; 6, CM phase referred to phase value of electrode 1, 7 CM phase measured against stimulus signal.

all twelve electrode outputs were recovered in this way Then the computer data were stored on magnetic tape.

This technique allowed the rapid collection of data. During a session of three to four hours the responses due to about 80 different stimuli could be measured. In terms of the previously employed techniques this meant taking 80 × 12 × 2 = 1 920 different accurate amplitude and phase readings—quite an impossible task even if there had not been any noise.

After the data collecting phase sinusoidal curves were fitted to the data stored on the magnetic tape and subsequently the computer printed out amplitude and phase values. (Here also the phase difference was measured between the reference signal (stimulus) and the output signal.) An example of such a print-out is given in Fig. 2.9

Since the cables leading from the laboratory to the computer room were quite long there was cross-talk from the reference channel to the signal channel. The 'ghost signal' in the signal channel due to cross-talk had a magnitude corresponding to a CM amplitude of 0.05 to 0.5 μV rms. In cases where the CM had a value in the region of 2 to 5 μV rms the ghost signal was measured separately and later subtracted from the compound signal. The ghost signal was determined by measuring the response in the idle signal channel, i.e. with no CM signal applied.

DISCUSSION OF TECHNIQUE

It is expedient to discuss at this point some questions relevant to the application of the multi-electrode technique. There are basically two aspects which need consideration. The one aspect is concerned with the question whether the mechanical performance of the cochlear system is disturbed due to the slit opening and the insertion of the probe into scala tympani. The other aspect relates to the problem whether the mechanical presence of the array in the scala distorts the potential field set up by hair-cell activity

According to Johnstone & Boyle (1967) the fluid level in scala tympani has negligible influence on the mechanical response of the basal part of the basilar membrane thus there was no difference in their results whether the perilymph was present or absent in the basal scala tympani (provided the basilar membrane was not dried out. Johnstone, 1969) This is consistent with von Békésy's observations (1960 *a*, p. 439) on dimensional models where the emptying of 'scala tympani' did not alter the position of the vibratory pattern manifested by the local stability of the circular eddy in scala vestibuli Further evidence for the negligible effect of slit-like openings in the cochlear wall on the excitation pattern comes from the experiments by Tasaki et al. (1952). These authors made a small opening in the

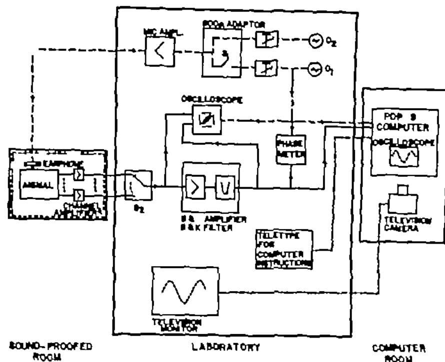

Fig 2.8 Block diagram of the ex perimental set-up. --- stimulus signal —— CM output signal —· reference signal (from stimulus); ——— Computer instructions and television link.

filtered CM response was read from the moni tor of the B & K amplifier The phase was determined in one of two ways. Feeding the output from the B & K amplifier into the oscilloscope together with the stimulus signal and displaying the Lissajous figures was one possibility In the other more accurate method a phase meter was employed. It measured the phase difference between the stimulus and the output signal The meter was built in this laboratory according to a circuit diagram published by Woodbury (1961) The accuracy of the meter was ±2 over the frequency range used in the experiments

For the graphical representation of the CM patterns the phase of the most basal electrode was taken as 'zero reference phase This was achieved simply by subtracting from all twelve phase readings the value measured for the most basal electrode.

An alternative method was adopted when it became necessary to measure the CM response at low SPLs (40 to 60 db) The output signals were too small and the noise in the recording system was too high for the previously described methods to work satisfactorily The recovery of the waveform of the output signal from noise was accomplished with the aid of a digital computer PDP 9 situated in the computer room. The scheme for the computer aided measurements was devised by my colleague, H. F Ross, who also wrote the computer programme The method was based on the technique known as signal averaging' The noisy signal was recurrently sampled at 50 successive points. The sampling points were so spaced in time as to cover one to two periods of the signal waveform Sampling was initiated by pulses derived from the zero-crossings of the reference signal which was provided by oscillator O_1 Corresponding samples from recurrent sweeps were added up thus reinforcing the periodic signal waveform at each repetition The signal waveform was displayed on the oscilloscope screen of the computer From there it was transmitted via a television link back to the laboratory In this way it was possible to observe the building up of the wave form of the output signal on the television screen during tonal stimulation The stimulus to the animal was turned off (by opening switch S_1) as soon as the waveform of the output showed a satisfactory sinusoidal shape of sufficient amplitude. For any given stimulus

Fig 2.9 Example of computer print out. (The data are drawn in Fig. 3.1.A, see 14.5 kHz record).
Key: Row *1*: Record 21, 30 db (corresponds to 85 db SPL), 14.50 kHz. Column *1*: electrode numbers 1 to 12, *2*: sine (electrode outputs); *3*: cosine (electrode output); *4*: CM amplitude in μV rms, *5*: $\log_{10}$ CM amplitude; *6*: CM phase referred to phase value of electrode 1, *7*: CM phase measured against stimulus signal.

all twelve electrode outputs were recovered in this way. Then the computer data were stored on magnetic tape.

This technique allowed the rapid collection of data. During a session of three to four hours the responses due to about 80 different stimuli could be measured. In terms of the previously employed techniques this meant taking $80 \times 12 \times 2 = 1\,920$ different accurate amplitude and phase readings—quite an impossible task even if there had not been any noise.

After the data collecting phase sinusoidal curves were fitted to the data stored on the magnetic tape and subsequently the computer printed out amplitude and phase values. (Here also the phase difference was measured between the reference signal (stimulus) and the output signal.) An example of such a print-out is given in Fig. 2.9.

Since the cables leading from the laboratory to the computer room were quite long there was cross-talk from the reference channel to the signal channel. The 'ghost signal' in the signal channel due to cross-talk had a magnitude corresponding to a CM amplitude of 0.05 to 0.5 μV rms. In cases where the CM had a value in the region of 2 to 5 μV rms the ghost signal was measured separately and later subtracted from the compound signal. The ghost signal was determined by measuring the response in the idle signal channel, i.e. with no CM signal applied.

DISCUSSION OF TECHNIQUE

It is expedient to discuss at this point some questions relevant to the application of the multi-electrode technique. There are basically two aspects which need consideration. The one aspect is concerned with the question whether the mechanical performance of the cochlear system is disturbed due to the slit opening and the insertion of the probe into scala tympani. The other aspect relates to the problem whether the mechanical presence of the array in the scala distorts the potential field set up by hair-cell activity.

According to Johnstone & Boyle (1967) the fluid level in scala tympani has negligible influence on the mechanical response of the basal part of the basilar membrane: thus there was no difference in their results whether the perilymph was present or absent in the basal scala tympani (provided the basilar membrane was not dried out. Johnstone, 1969). This is consistent with von Békésy's observations (1960 *a* p. 439) on dimensional models where the emptying of 'scala tympani' did not alter the position of the vibratory pattern manifested by the local stability of the circular eddy in 'scala vestibuli'. Further evidence for the negligible effect of slit-like openings in the cochlear wall on the excitation pattern comes from the experiments by Tasaki et al. (1952). These authors made a small opening in the

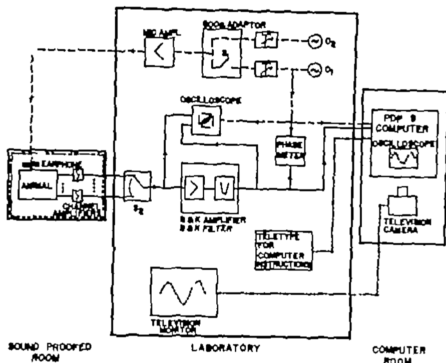

Fig 2.8 Block diagram of the experimental set up. --- stimulus signal —— CM output signal, — reference signal (from stimulus) -·-·- Computer instructions and television link.

filtered CM response was read from the monitor of the B & K amplifier The phase was determined in one of two ways Feeding the output from the B & K amplifier into the oscilloscope together with the stimulus signal and displaying the Lissajous figures was one possibility In the other more accurate method a phase meter was employed It measured the phase difference between the stimulus and the output signal. The meter was built in this laboratory according to a circuit diagram published by Woodbury (1961) The accuracy of the meter was ±2 over the frequency range used in the experiments.

For the graphical representation of the CM patterns the phase of the most basal electrode was taken as 'zero reference phase This was achieved simply by subtracting from all twelve phase readings the value measured for the most basal electrode

An alternative method was adopted when it became necessary to measure the CM response at low SPLs (40 to 60 db) The output signals were too small and the noise in the recording system was too high for the previously described methods to work satisfactorily The recovery of the waveform of the output signal from noise was accomplished with the aid of a digital computer PDP-9 situated in the computer room The scheme for the computer aided measurements was devised by my colleague, H. F Ross, who also wrote the computer programme The method was based on the technique known as 'signal averaging The noisy signal was recurrently sampled at 50 successive points. The sampling points were so spaced in time as to cover one to two periods of the signal waveform Sampling was initiated by pulses derived from the zero-crossings of the reference signal which was provided by oscillator O_1 Corresponding samples from recurrent sweeps were added up thus reinforcing the periodic signal waveform at each repetition The signal waveform was displayed on the oscilloscope screen of the computer From there it was transmitted via a television link back to the laboratory In this way it was possible to observe the building up of the waveform of the output signal on the television screen during tonal stimulation The stimulus to the animal was turned off (by opening switch S_1) as soon as the waveform of the output showed a satisfactory sinusoidal shape of sufficient amplitude For any given stimulus

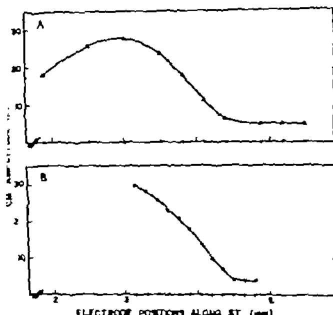

Fig. 2.10 CM amplitude pattern at 1 kHz, 90 db SPL measured in two different guinea pigs. (Electrode position along scala tympani, ST is given.)

(A) Pattern obtained with the single electrode technique (ten different electrodes).

(B) Pattern obtained with the 'multi-electrode' technique. The two different techniques gave the same results over the region studied.

a distortion of the eddy in 'scala tympani' however the eddy in 'scala vestibuli' remained unchanged. This effect seemed to be related to the narrowing of 'scala tympani' due to the presence of the object and von Békésy concluded 'that nature had made the depth of the duct as small as possible without going so far as to cause a spreading out of the vibratory pattern along the cochlear partition'. Since in our experiments there was sufficient free space between the actual array and the borders of the slit one would assume that the array did not effectively narrow the canal.

The other major question which needs consideration is concerned with the influence the mechanical presence of the array might have on the potential field in the scala. As shown in Fig. 2.10 both techniques employed in the study with their very different electrode arrangements gave the same results, hence it seems very unlikely that the array probe significantly distorts the potential field. In Fig. 2.11 A. the results from another test experiment are displayed. The CM potentials were measured for the same stimulus at two different depths of insertion of the probe into scala tympani. Thus the length of the array tip inserted in the scala was different for the two measurements. There are only very slight differences between the patterns acquired from different depths and we may assume that these differences are due to the conductive properties of the inner ear rather than the different lengths with which the array projects into the scala. Yet another piece of evidence is illustrated in Fig. 2.11 B. Here the CM pattern of an 8 kHz tone was registered. (The animal was exposed previously to a traumatic tone of 13 kHz; this explains the peculiar shape of the pattern. See Section 3 Tonal Overstimulation.) This pattern was chosen for the test experiment because there was a large phase shift between electrodes 5 and 6. The array was translated by a small amount in the longitudinal direction and the CM response to the same stimulus was measured again. As shown in the illustration we obtained essentially the same pattern, displaced however in the longitudinal direction. The large phase shift occurs now between electrodes 3 and 4. This is convincing evidence that the electrode probe itself had practically no influence on the results and can be regarded as a passive sensing device meeting the purpose for which it was intended.

wall of scala vestibuli in the second turn of the guinea pig's cochlea and they monitored the CM response in the third turn before and after the manufacture of the hole. Due to the hole the CM response dropped only by an amount of 3 to 4 db. (Tasaki et al. came to the very interesting conclusion that a considerable portion of the acoustic energy must be transmitted to the upper parts of the cochlea by means of longitudinal coupling in the membrane. This is important since mathematical models of cochlear hydrodynamics usually neglect coupling forces between the transverse elements of the basilar membrane (see Zwislocki, 1953).) It is difficult to judge whether the hole produced a complete release of the pressure wave in the fluid column of scala vestibuli and therefore prevented energy transport via the fluid medium to the regions apical to the hole. If this was the case the conclusion of Tasaki et al. would be necessary. Despite the fact that the hole had an area almost as large as the canal cross section it would probably be more realistic to visualize the effect of the hole as that of a 'hydraulic filter' with frequency dependent characteristics. On the basis of this assumption one would predict the occurrence of a large attenuation of the apical signal in cases where the wavelength of the pressure wave approaches the dimensions of the hole, i.e. at high frequencies where the wavelength is sufficiently short. Tasaki et al. reported that 'for all the frequencies employed the drop in potential in the third turn was the same. However, in the case of a hole (width 200 μ) connecting the basal scala vestibuli with the scala tympani of the second turn they recorded an equal change of the apical potential for frequencies below 800 Hz' this we may assume could mean that at higher frequencies apical potentials were relatively more affected. The problem of which medium—the membrane or the fluid—is mainly responsible for the energy transport is extremely difficult to solve with experiments like those of Tasaki et al. Not only can an opening influence the hydrodynamics of the system but it can also influence the recording situation: due to the outflow of perilymph from the opening there exists the possibility of electrical cross-connections between channels via the electrode holes. Clearly, the necessity to keep these two effects separate seriously narrows the range of possible spatial configurations of electrode positions and opening positions.)

Evidence for the negligible influence of the slit in the wall of the basal scala tympani on the functioning of the cochlea is provided by the present study. Fig. 2.10 shows the CM amplitude patterns obtained from two different guinea pigs for the same stimulus parameters. The one curve was measured with the single electrode technique, i.e. ten electrodes were essentially sealed into the holes in the wall of scala tympani. The other curve was recorded with the multi-electrode technique, i.e. the electrode array was inserted through the slit into scala tympani. It can be seen that both techniques produced the same result.

The weight of the evidence mentioned so far seems to support the view that the effect of the opening in the basal part of scala tympani can be neglected. However, there is a statement in the literature (von Békésy & Rosenblith, 1951, p. 1105; von Békésy 1960 *b*, p. 92) that a circular eddy occurs at any opening in the cochlear wall under strong tonal stimulation. It is stated further that covering the opening with a glass plate and immersing the whole preparation in fluid reduces the eddy to a great extent. In our experiments a considerable amount of perilymph was allowed to collect above the slit opening. Whether this fluid column above scala tympani had an effect similar to that of the measures taken by von Békésy is, of course, impossible to decide on the basis of CM recordings.

A further point concerns the fact that the array tip was inserted into scala tympani so that a mechanical object was present in the tympanic channel. This situation is similar to some extent to the model study of von Békésy (1960 *a*, p. 437) where a 'small object was placed in scala tympani'. Von Békésy observed

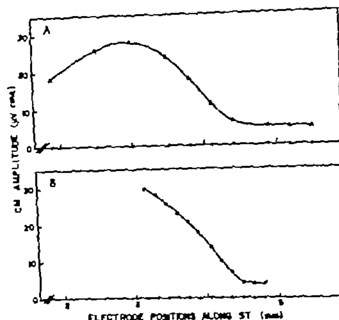

Fig. 2.10 CM amplitude pattern at 12 kHz, 90 db SPL, measured in two different guinea pigs. (Electrode position along scala tympani, ST is given.)

(A) Pattern obtained with the 'single electrode technique (two different electrodes).

(B) Pattern obtained with the 'multi-electrode technique. The two different techniques gave the same results over the region studied.

a distortion of the eddy in scala tympani' however the eddy in 'scala vestibuli remained unchanged. This effect seemed to be related to the narrowing of 'scala tympani' due to the presence of the object and von Békésy concluded 'that nature had made the depth of the duct as small as possible without going so far as to cause a spreading out of the vibratory pattern along the cochlear partition Since in our experiments there was sufficient free space between the actual array and the borders of the slit one would assume that the array did not effectively narrow the canal.

The other major question which needs consideration is concerned with the influence the mechanical presence of the array might have on the potential field in the scala. As shown in Fig. 2.10 both techniques employed in the study with their very different electrode arrangements gave the same results, hence it seems very unlikely that the array probe significantly distorts the potential field. In Fig. 2.11 A the results from another test experiment are displayed. The CM potentials were measured for the same stimulus at two different depths of insertion of the probe into scala tympani. Thus the length of the array tip inserted in the scala was different for the two measurements. There are only very slight differences between the patterns acquired from different depths and we may assume that these differences are due to the conductive properties of the inner ear rather than the different lengths with which the array projects into the scala. Yet another piece of evidence is illustrated in Fig. 2.11 B Here the CM pattern of an 8 kHz tone was registered. (The animal was exposed previously to a traumatic tone of 13 kHz; this explains the peculiar shape of the pattern. See Section 3 Tonal Overstimulation.) This pattern was chosen for the test experiment because there was a large phase shift between electrodes 5 and 6. The array was translated by a small amount in the longitudinal direction and the CM response to the same stimulus was measured again. As shown in the illustration we obtained essentially the same pattern, displaced however in the longitudinal direction. The large phase shift occurs now between electrodes 3 and 4. This is convincing evidence that the electrode probe itself had practically no influence on the results and can be regarded as a passive sensing device meeting the purpose for which it was intended.

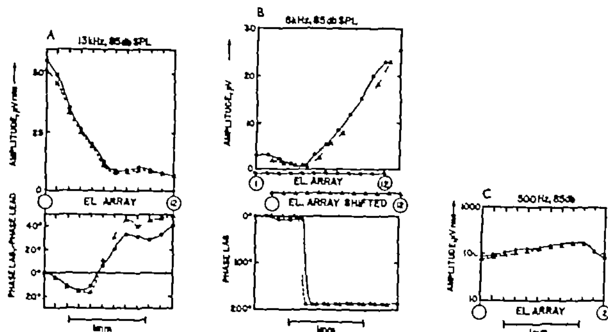

Fig. 2.11 (A) CM amplitude and phase pattern at 13 kHz, 85 db SPL. The array was inserted to a depth of 400 μ (●—●) and 300 μ (▲—▲) into scala tympani. There is very little difference between the CM patterns measured at different depths.

(B) CM amplitude and phase pattern at 8 kHz, 85 db SPL (after overstimulation with a tone of 13 kHz, 130 db for 3 min). The electrode array was translated in the apical direction by approximately 100 μ and essentially the same CM pattern was obtained. The large phase shift between electrodes 5 and 6 occurred after the translation between electrodes 3 and 4. ●—● Pattern before translation ▲—▲, pattern after translation.

(C) CM amplitude patterns obtained from two different guinea pigs for the same stimulus (500 Hz, 85 db SPL). The two curves are almost identical. ●—● first guinea pig. ▲—▲ second guinea pig. In (A), (B), (C), electrodes are numbered from 1 to 12 beginning with the most basal electrode.

Additional support for the validity of the CM recordings taken with the electrode array derives from the fact that each of the twelve electrode outputs had exactly the same properties as the CM recorded in the normal way by other workers with only one or two electrodes in the basal turn. This concerns the magnitude of the potentials and the intensity function. It suggests that the slit technique does not disturb the system more than the traditional technique with only a few small holes.

Theoretically speaking the multi-electrode technique cannot itself provide the answer to the question whether it causes disturbance in the cochlear system since such an answer requires the knowledge of the CM distribution in the completely undisturbed cochlea for comparison. The evidence presented above strongly suggests a negligible interference of the technique with the functions of the cochlea, but even if there was interference the technique would still be useful provided the interference was stable from experiment to experiment. The question of reproducibility of results was one of major concern in this study since any uncontrolled variability in the CM patterns would make the quantitative investigation of the spatial filter effect completely impossible. The great pains taken both with the surgery and the equipment to set up the experiment proved worth while in the long run. In Fig. 2.11 C two CM amplitude patterns from different guinea pigs are shown for the same stimulus parameters. It can be seen that the curves are almost identical. Thus experiments yielded reproducible data.

3 Results

The hypothesis to be tested by the experiments describes the cochlear *microphonic distribution* along the cochlear ducts as the spatially filtered version of the hair-cell activity along the basilar membrane.

$$CM(x) = \int_{-\infty}^{\infty} H(z)\, W(x-z)\, dz = H(x) * W(x) \quad (1)$$

Equation (1) shows the connection between $H(x)$ and $CM(x)$ for any arbitrary auditory stimulus. In our experiments sinusoidal stimuli were used and we may adopt the trigonometric or the alternative exponential notation to specify $H(x)$.

Sinusoidal stimulation of the inner ear causes travelling wave motion along the cochlear partition. The mechanical excursions of the partition activate the hair-cell generators. *We may represent the electrical output of any* such unit generator situated at a point x along the basilar membrane in terms of a Fourier series. For an external stimulus of angular frequency ω this series takes the form.

$$h(x_a, t) = A_0(x_a) + \sum_1^{\infty} A_n(x_a) \cos(n\omega t - B_n(x_a)) \quad (2a)$$

The expression (2 *a*) indicates that the electrical output at x may contain harmonic components due to nonlinearities in the transducer system. Since the space variable x assumes all *values x along the basilar membrane* $h(x, t)$ denotes the spatial distribution of the electrical output along the membrane:

$$h(x, t) = A_0(x) + \sum_1^{\infty} A_n(x) \cos(n\omega t - B_n(x)) \quad (2b)$$

or when written in exponential form

$$h(x, t) = A_0(x) + \sum_1^{\infty} \mathrm{Re}[A_n(x)\, e^{-jB_n(x)}\, e^{jn\omega t}] \quad (2c)$$

We obtain the instantaneous distribution of electrical *potentials along the cochlear scalae* $cm(x, t)$ by spatially filtering $h(x, t)$

$$cm(x, t) = \int_{-\infty}^{\infty} [A_0(z) + \sum_1^{\infty} \mathrm{Re} \times (A_n(z)\, e^{-jB_n(z)}\, e^{jn\omega t})]\, W(x-z)\, dz \quad (3a)$$

The time-dependent factors in (3 *a*) are unaffected by the spatial integration and we can write:

$$cm(x, t) = \int_{-\infty}^{\infty} A_0(z)\, W(x-z)\, dz + \sum_1^{\infty} \mathrm{Re} \times \left[e^{jn\omega t} \int_{-\infty}^{\infty} A_n(z)\, e^{-jB_n(z)}\, W(x-z)\, dz\right]$$

with $\int_{-\infty}^{\infty} A_0(z)\, W(x-z)\, dz = Q_0(x)$

$$\int_{-\infty}^{\infty} A_n(z)\, e^{-jB_n(z)}\, W(x-z)\, dz = Q_n(x)\, e^{-jP_n(x)}$$

It follows

$$cm(x, t) = Q_0(x) + \sum_1^{\infty} \mathrm{Re}[Q_n(x)\, e^{-jP_n(x)}\, e^{jn\omega t}]$$

$$cm(x, t) = Q_0(x) + \sum_1^{\infty} Q_n(x) \cos(n\omega t - P_n(x)) \quad (3b)$$

With a set *of sensing* electrodes placed along the cochlear duct the potential distribution $cm(x, t)$ can be recorded. By extracting the fundamental frequency of the electrode outputs we obtain the distribution of the fundamental *component.*

$$cm(x, t) = Q_1(x) \cos(\omega t - P_1(x)) \quad (4)$$

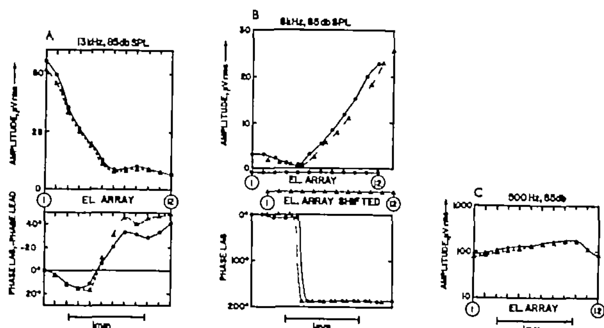

Fig 2 11 (A) CM amplitude and phase pattern at 13 kHz, 85 db SPL. The array was inserted to a depth of 400 μ (●—●) and 300 μ (▲—▲) into scala tympani. There is very little difference between the CM patterns measured at different depths.

(B) CM amplitude and phase pattern at 8 kHz, 85 db SPL (after overstimulation with a tone of 13 kHz, 130 db for 3 min) The electrode array was translated in the apical direction by approximately 200 μ and essentially the same CM pattern was obtained. The large phase shift between electrodes 5 and 6 occurred after the translation between electrodes 3 and 4. ●—● Pattern before translation ▲—▲ pattern after translation.

(C) CM amplitude patterns obtained from two different guinea pigs for the same stimulus (500 Hz, 85 db SPL). The two curves are almost identical ●—● first guinea pig. ▲—▲ second guinea pig. In (*A*), (*B*), (*C*) electrodes are numbered from 1 to 12 beginning with the most basal electrode.

Additional support for the validity of the CM recordings taken with the electrode array derives from the fact that each of the twelve electrode outputs had exactly the same properties as the CM recorded in the normal way by other workers with only one or two electrodes in the basal turn This concerns the magnitude of the potentials and the intensity function It suggests that the slit technique does not disturb the system more than the traditional technique with only a few small holes.

Theoretically speaking the multi-electrode technique cannot itself provide the answer to the question whether it causes disturbance in the cochlear system since such an answer requires the knowledge of the CM distribution in the completely undisturbed cochlea for comparison The evidence presented above strongly suggests a negligible interference of the technique with the functions of the cochlea but even if there was interference the technique would still be useful provided the interference was stable from experiment to experiment The question of reproducibility of results was one of major concern in this study since any uncontrolled variability in the CM patterns would make the quantitative investigation of the spatial filter effect completely impossible The great pains taken both with the surgery and the equipment to set up the experiment proved worth while in the long run In Fig 2 11 C two CM amplitude patterns from different guinea pigs are shown for the same stimulus parameters It can be seen that the curves are almost identical Thus experiments yielded reproducible data.

3 Results

The hypothesis to be tested by the experiments describes the cochlear microphonic distribution along the cochlear ducts as the spatially filtered version of the hair-cell activity along the basilar membrane.

$$CM(x) = \int_{-\infty}^{\infty} H(z)\, W(x-z)\, dz = H(x) * W(x) \quad (1)$$

Equation (1) shows the connection between $H(x)$ and $CM(x)$ for any arbitrary auditory stimulus. In our experiments sinusoidal stimuli were used *and we may adopt* the trigonometric or the alternative exponential notation to specify $H(x)$.

Sinusoidal stimulation of the inner ear causes travelling wave motion along the cochlear partition. The mechanical excursions of *the partition activate the hair-cell generators.* We may represent the electrical output of any such unit generator situated at a point x_a along the basilar membrane in terms *of a* Fourier series. For an external stimulus of angular frequency ω this series takes the form.

$$h(x_a, t) = A_0(x_a) + \sum_{1}^{\infty} A_n(x_a) \cos(n\omega t - B_n(x_a)) \quad (2a)$$

The expression (2 *a*) indicates that the electrical output at x_a may contain harmonic components due to nonlinearities in the transducer system. Since the space variable x assumes all values x_a along the basilar membrane $h(x, t)$ denotes the spatial distribution of the electrical output along the membrane:

$$h(x, t) = A_0(x) + \sum_{1}^{\infty} A_n(x) \cos(n\omega t - B_n(x)) \quad (2b)$$

or when written in exponential form

$$h(x, t) = A_0(x) + \sum_{1}^{\infty} \mathrm{Re}[A_n(x)\, e^{-jB_n(x)}\, e^{jn\omega t}] \quad (2c)$$

We obtain the instantaneous distribution of electrical potentials along the cochlear scalae $cm(x, t)$ by spatially filtering $h(x, t)$:

$$cm(x, t) = \int_{-\infty}^{\infty} [A_0(z) + \sum \mathrm{Re}$$

$$\times (A_n(z)\, e^{-jB_n(z)}\, e^{jn\omega t})]\, W(x-z)\, dz \quad (3a)$$

The time-dependent factors in (3 *a*) are unaffected by the spatial integration and we can write:

$$cm(x, t) = \int_{-\infty}^{\infty} A_0(z)\, W(x-z)\, dz + \sum_{1}^{\infty} \mathrm{Re}$$

$$\times \left[e^{jn\omega t} \int_{-\infty}^{\infty} A_n(z)\, e^{-jB_n(z)}\, W(x-z)\, dz\right]$$

with

$$\int_{-\infty}^{\infty} A_0(z)\, W(x-z)\, dz = Q_0(x)$$

$$\int_{-\infty}^{\infty} A_n(z)\, e^{-jB_n(z)}\, W(x-z)\, dz = Q_n(x)\, e^{-jP_n(x)}$$

it follows

$$cm(x, t) = Q_0(x) + \sum_{1}^{\infty} \mathrm{Re}[Q_n(x)\, e^{-jP_n(x)}\, e^{jn\omega t}]$$

$$cm(x, t) = Q_0(x) + \sum_{1}^{\infty} Q_n(x) \cos(n\omega t - P_n(x)) \quad (3b)$$

With a set of sensing electrodes placed along the cochlear duct the potential distribution $cm(x, t)$ can be recorded. By extracting the fundamental frequency of the electrode outputs we obtain the distribution of the fundamental component.

$$cm(x, t) = Q_1(x) \cos(\omega t - P_1(x)) \quad (4)$$

The amplitude distribution $Q_1(x)$ and the phase distribution $P_1(x)$ *define the spatial distribution* of the fundamental component of the cochlear microphonic. Both parameter distributions can be determined experimentally by measuring the amplitude and phase values of all electrode outputs.

Since we are only interested in the amplitude and phase distributions it is preferable to use the exponential instead of the trigonometric notation. It is permissible to omit the time variable because it does not enter calculations. It therefore suffices to write

$$\mathrm{CM}_1(x) = \int_{-\infty}^{\infty} H_1(x)\, W(x-z)\, dz = H_1(x) * W(x) \qquad (5)$$

$$\mathrm{CM}_1(x) = Q_1(x)\, e^{jP_1(x)} \qquad (5a)$$

$$H_1(x) = A_1(x)\, e^{j\varphi_1(x)} \qquad (5b)$$

The expressions in (5 a) and 5 b) show the essential parameter distributions involved in the spatial filtering operation. The amplitude and phase distributions of the cochlear microphonic are related to the amplitude and phase distributions of the hair-cell outputs according to equation (5). Multiplication of equation (5) with a constant reference phase factor $\exp(jP)$ has no influence on the spatial integration. It is therefore permissible to refer the phase readings of the electrode outputs to any arbitrary phase value. In the following diagrams the output phases are always referred to the phase value of the most basal electrode. Since in our experiments we exclusively considered the fundamental component of the cochlear microphonic we may simplify the notation in the text. Thus, with $H(x)$ we mean the spatial distribution of the fundamental component of the hair-cell outputs in response to sinusoidal stimuli. $\mathrm{CM}(x)$ or $\mathrm{CM}(x_0)$ denotes the longitudinal distribution of the fundamental component of the cochlear microphonic in response to sinusoidal stimuli.

All CM patterns displayed in this section were obtained with the multi-electrode array. The most basal electrode of the array was always located in the region of 3 to 3.5 mm, *measuring* from the basal end of the basilar membrane. In the graphs the space coordinate is indicated by the electrode positions (see Fig. 3 1 B). It is expedient for the discussion of the CM patterns to express the space coordinate in terms of electrode numbers. Thus the electrodes of the array are numbered from 1 to 12 beginning with the most basal electrode.

A. THE DESCRIPTION OF DATA

CM amplitude and phase patterns

Experiments were carried out by measuring the amplitude and phase distribution of the CM along the electrode array for tonal stimuli of different frequencies. In all experiments we obtained response patterns with the same basic properties, all characteristic features of the distributions being reproducible in different guinea pigs.

Fig. 3 1 A shows a typical example of a set of CM patterns from one guinea pig: the patterns were measured at frequencies from 500 Hz to 15.5 kHz and a constant SPL of 85 db. The low frequency (500 Hz) record can be used as a control of the preparation and the uniformity of the sensing electrodes. At this frequency all individual electrodes composing the array are essentially equidistant from the maximum excitation which occurs in the apical portion of the cochlea. The wave length in the basal part of the excitation pattern is very long compared to the array width and we may therefore expect very little phase variation along the array. This expectation is confirmed by the 500 Hz record which shows negligible phase change between electrodes. Due to the long wavelength of the excitation pattern there is practically no phase cancellation in the region of the array and consequently the CM amplitude pattern has an appearance similar to that of the basal part of the envelope of the excitation pattern. Thus the amplitude in the 500 Hz pattern grows continuously in the apical direction. However at electrodes 11 and 12 the amplitude declines,

a feature observed in the majority of the preparations. The drop in potential is probably an artefact due to the strong curvature of the basilar membrane and the scala tympani in this region. Electrode tips are arranged in the array in a straight line which approximates to the curved course of the cochlear partition and cochlear canals over a short distance only. In terms of the array configuration the cochlear canals take a sharp bend away from the array in the region of electrodes 11 and 12. Thus 11 and 12 are the electrodes dislocated most from the ideal line following the longitudinal course of the membrane. It can be seen in the 500 Hz record that there is practically no alteration in the phase pattern at 11 and 12. This also indicates that the drop in amplitude at 11 and 12 is due to the placement of the array rather than phase cancellation. This conclusion results from the fact that in all high frequency records—where phase cancellation is manifest—amplitude variations are always accompanied by marked phase variations.

The goodness of a preparation may be judged on the basis of low frequency records because the expected patterns are simple and deviations from the normal response stand out clearly enough to allow rapid judgement. However, with the experience accumulated over many experiments it was possible to estimate the quality of preparations by considering the CM pattern at any frequency between 500 Hz and 15 kHz.

CM patterns take a more complicated form as the stimulus frequency is increased. The maximum of the excitation pattern along the membrane moves progressively towards the basal end of the cochlea with increasing frequency; the wavelengths of the excitation pattern become progressively shorter and this means that the phase lag gradient (phase change per unit length) along the partition increases with frequency. Closely neighbouring hair-cells are driven out of phase and consequently there will be negative interference—mutual cancellation of hair-cell outputs in the surrounding liquid spaces. The total number of hair-cells activated is probably smaller at high frequencies than at low ones because the excitation pattern is confined to a relatively shorter length of membrane. The general tendency of the CM amplitude to decrease when the stimulus frequency is raised can be read from Fig. 3.1.A. This tendency is probably due to the combined effect of the reduction in the number of activated hair-cells and the growing influence of phase cancellation with increasing frequency.

The CM amplitude distributions undergo characteristic changes with increasing stimulus frequency. Electrodes in the distant part of the array show relatively more drop in potential than do the proximal electrodes. The low level of the distant amplitudes is maintained when 15 kHz is exceeded and this observation indicates that the bulk of the excitation occurs in the region basal to this part of the array, that is at frequencies beyond 15 kHz. The most interesting feature, however, is the occurrence of a distinct amplitude minimum, well shown in the records at frequencies around 14 kHz.

The CM phase gradient along the array increases progressively with stimulus frequency (as shown in the records from 500 Hz to 12 kHz); thus at 12 kHz there is an overall phase difference between electrodes 1 and 12 of 196°. In the 13.5 kHz record this phase difference amounts to 258°; however, the shape of the CM phase distribution is clearly different from that in the 12 kHz record. The phase gradient is small in the proximal and distal parts of the array while it is large in the region of the amplitude minimum. The co-occurrence of an amplitude minimum and a large phase gradient is a characteristic property of CM patterns at high frequencies, in the present example at frequencies around 13.5 kHz.

At 13.75 kHz the phase gradient in the region of the amplitude minimum is even greater than at 13.5 kHz. The phase difference between electrodes 6 and 7 has a value of 143°. Clearly this is an enormous local varia-

The amplitude distribution $Q_1(x)$ and the phase distribution $P_1(x)$ define the spatial distribution of the fundamental component of the cochlear microphonic. Both parameter distributions can be determined experimentally by measuring the amplitude and phase values of all electrode outputs

Since we are only interested in the amplitude and phase distributions it is preferable to use the exponential instead of the trigonometric notation. It is permissible to omit the time variable because it does not enter calculations. It therefore suffices to write

$$\mathrm{CM}_1(x) = \int_{-\infty}^{\infty} H_1(x)\, W(x - \ )\, d = H_1(x) * W(x) \quad (5)$$

$$\mathrm{CM}_1(x) = Q_1(x)\, e^{jP_1(x)} \quad (5a)$$

$$H_1(x) = A_1(x)\, e^{jP_1(x)} \quad (5b)$$

The expressions in (5 *a*) and 5 *b*) show the essential parameter distributions involved in the spatial filtering operation The amplitude and phase distributions of the cochlear microphonic are related to the amplitude and phase distributions of the hair-cell outputs according to equation (5) Multiplication of equation (5) with a constant reference phase factor exp(*jP*) has no influence on the spatial integration It is therefore permissible to refer the phase readings of the electrode outputs to any arbitrary phase value In the following diagrams the output phases are always referred to the phase value of the most basal electrode Since in our experiments we exclusively considered the fundamental component of the cochlear microphonic we may simplify the notation in the text Thus, with $H(x)$ we mean the spatial distribution of the fundamental component of the hair-cell outputs in response to sinusoidal stimuli. CM(x) or CM(x_0) denotes the longitudinal distribution of the fundamental component of the cochlear microphonic in response to sinusoidal stimuli

All CM patterns displayed in this section were obtained with the multi-electrode array The most basal electrode of the array was always located in the region of 3 to 3.5 mm measuring from the basal end of the basilar membrane In the graphs the space coordinate is indicated by the electrode positions (see Fig 3 1 B) It is expedient for the discussion of the CM patterns to express the space coordinate in terms of electrode numbers. Thus the electrodes of the array are numbered from 1 to 12 beginning with the most basal electrode

A THE DESCRIPTION OF DATA

CM amplitude and phase patterns

Experiments were carried out by measuring the amplitude and phase distribution of the CM along the electrode array for tonal stimuli of different frequencies. In all experiments we obtained response patterns with the same basic properties, all characteristic features of the distributions being reproducible in different guinea pigs.

Fig 3 1 A shows a typical example of a set of CM patterns from one guinea pig the patterns were measured at frequencies from 500 Hz to 15.5 kHz and a constant SPL of 85 db Thu low frequency (500 Hz) record can be used as a control of the preparation and the uniformity of the sensing electrodes. At this frequency all individual electrodes composing the array are essentially equidistant from the maximum excitation which occurs in the apical portion of the cochlea. The wave length in the basal part of the excitation pattern is very long compared to the array width and we may therefore expect very little phase variation along the array Thus expectation is confirmed by the 500 Hz record which shows negligible phase change between electrodes. Due to the long wavelength of the excitation pattern there is practically no phase cancellation in the region of the array and consequently the CM amplitude pattern has an appearance similar to that of the basal part of the envelope of the excitation pattern Thus the amplitude in the 500 Hz pattern grows continuously in the apical direction However at electrodes 11 and 12 the amplitude declines,

B

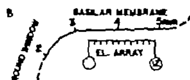

Fig. 3.1 (A) Typical example of a set of CM amplitude and phase patterns measured in one guinea pig. Note the co-occurrence of an amplitude minimum and a large phase gradient in the 13.5 kHz and 13.75 kHz record. CM phase patterns beyond 13.75 kHz show phase reversal.

(B) Position of electrode array (*EL. ARRAY*) in relation to the length coordinate of the basilar membrane. ——, amplitude; – – –, phase.

and phase data are considered in combined vector form. If the phase pattern is considered alone like in Fig. 3.1.A, the transition from the 13.75 kHz to the 14 kHz phase pattern appears to be an abrupt event, and therefore, quite irritating to the observer.

A simple model can be given to explain the transition from a trajectory with progressive

tion considering that the interelectrode distance is only 150 μ The appearance of the phase pattern changes abruptly when the stimulus frequency exceeds 13 75 kHz. Thus at 14 kHz the distant part of the array definitely leads the proximal part in phase This phase reversal in the CM pattern at high frequencies can only be observed by means of closely spaced electrodes. The technique of Tasaki et al. (1952) with only two recording points in the basal coil of the cochlea is completely inadequate for the study of the CM phase variation at high frequencies. The single electrode technique described in Section 2, with a minimum distance of 300 μ between electrodes was not good enough for the recording of complicated phase patterns like those displayed in the records from 14 kHz to 15.5 kHz. Comparison between the phase patterns at 15 kHz and at 15 5 kHz reveals a distinct shift of the 'zero-crossings maxima and minima of the 15.5 kHz phase patterns by about one electrode distance in the basal direction The overall phase variation along the array decreases noticeably from 14.5 kHz to 15.5 kHz.

We may summarize those features of the CM patterns which are most important for the demonstration of the spatial filter effect 1) Amplitude minima are always accompanied by large changes in phase between adjacent electrodes. 2) Phase reversal occurs at high stimulus frequencies and distant electrodes may lead proximal ones in phase

CM patterns in vector form

CM patterns represent complex functions of the real space variable x since they comprise two parameter distributions, those of amplitude and phase The two distributions may be plotted separately as shown in Fig 3 1.A, or they may be combined in a single 3-dimensional graph with the dimensions of the graph given by a set of complex planes arranged along the space coordinate x This is because an electrode output at x_n can be visualized as a complex number or a vector in the complex plane at x with the amplitude and phase value of the electrode output representing the vector length and vector phase angle respectively Thus it is easy to imagine the CM distribution as a line connecting the endpoints of the output vectors in the complex planes at the electrode positions 1 to 12. However for the purposes of the present discussion it is sufficient to consider the projection of this line into a single complex plane, say the plane at electrode 1 We may conveniently call the projected version of the CM distribution the vector representation or 'vector form It is constructed by simply plotting all twelve output vectors in the same plane and by joining the vector endpoints through a trajectory (For completeness of the definition it may be mentioned that this trajectory denotes the projection of the complex CM distribution into a single plane.)

In Fig. 3 2.A, B C the data from Fig 3 1 A are redrawn in vector form for the stimulus frequencies 13.5 13 75 and 14 kHz. Phase reversal occurs in this frequency region and the vectorial representation of data is best suited to illustrate this phenomenon At 13.5 kHz the CM pattern exhibits progressive phase lag along the array from 1 to 12. By measuring the phase lag in the clockwise direction we obtain for the 13.5 kHz record a trajectory which encircles the origin of the vector plane Clearly any trajectory characterised by a progressive phase lag encircles the origin With increasing stimulus frequency the trajectory approaches and eventually crosses the origin After crossing phase reversal within the vector bundle must occur because the trajectory no longer encircles the origin Thus in the 14 kHz record there is no encirclement of the origin and it can be seen that the phase reverses between electrodes 5 and 6 electrode 6 leading in phase electrode 5

Vector representation of the data discloses the occurrence of the phase reversal with increasing frequency as the result of a simple, continuous process. This is due to the fact that in this representation the CM amplitude

and phase data are considered in combined vector form. If the phase pattern is considered alone, like in Fig. 3.1.A, the transition from the 13.75 kHz to the 14 kHz phase pattern appears to be an abrupt event, and therefore, quite irritating to the observer.

A simple model can be given to explain the transition from a trajectory with progressive

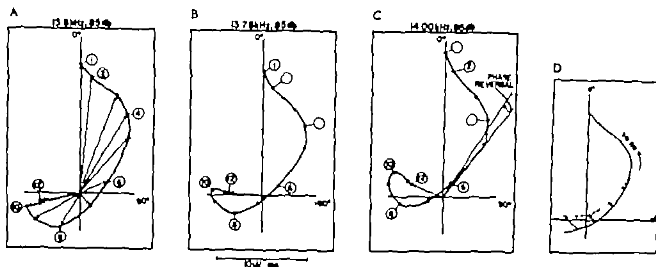

Fig 3.2 (A–C) Records (13.5 kHz, 13 75 kHz, 14 kHz) from Fig. 3 1.A redrawn in vector form. In (A) all output vectors are shown In (B) and (C) all vectors apart from 1 and 12 are omitted for clarity The trajectory connects all vector endpoints. Phase lag is counted in the clockwise direction The trajectory approaches with increasing frequency the origin of the vector plane note the concomitant increase in phase difference between 6 and 7 In (C) phase reversal occurs, 6 leading 5 in phase. In (A) and (B) the trajectory encircles the origin In (C) it does not.

(D) Artificially induced phase reversal by addition of small vector with large phase lag and amplitude which declines as the round window (*RW*) end of the array is approached

phase lag (13 75 kHz) into one with phase reversal (14 kHz) This is illustrated in the schematic drawing of Fig 3 2.D Let us add to all electrode outputs in a pattern like the one at 13 75 kHz a small vector with a large phase lag and a length which declines as the basal end of the array is approached The resulting trajectory has an appearance like the one at 14 kHz, i e it does not encircle the origin Something analogous to this vector addition may be expected to happen in reality As the stimulus frequency is increased from 13 75 to 14 kHz the wavelengths in the excitation pattern will shorten and a small group of distant hair-cells will be operating with slightly larger phase lag than before The influence of these distant hair-cell outputs is of course felt with an amplitude which declines towards the basal end of the array The model provides a qualitative explanation for the observed phase reversal and it suggests the far reaching influence of alterations in the outputs of subsets of hair-cell operators on the appearance of the whole CM pattern an influence postulated by the spatial filter hypothesis

A further point which deserves to be mentioned concerns the situation where the trajectory actually crosses the origin This situation was thoroughly explored in a preparation where one electrode of the array recorded very nearly zero amplitude in the frequency region of the phase reversal Thus this electrode output, when plotted on the trajectory very nearly coincided with the origin of the vector plane. The output of this electrode was displayed on the oscilloscope screen and a faint sinusoidal signal was just noticeable in the background noise It was interesting to observe that the output signal was extremely unstable shifting abruptly back and forth by about 180 on the oscilloscope screen All other electrode outputs however were perfectly stable This finding although it may seem strange at first glance can be interpreted quite plausibly Consideration of Fig 3 2 shows that the phase difference between the adjacent electrodes 6 and 7 grows continuously when the trajectory approaches the origin When the trajectory crosses the origin this phase difference becomes approximately 180 Thus a point in the immediate vicinity of the origin intermediate to 6 and 7 is framed by two vector bundles ap-

proximately 180° out of phase with each other This situation may be visualized as an unstable equilibrium, any small disturbance causing the small intermediate vector to shift to either of the two bundles.

B. THE ANALYSIS OF DATA

The spatial filter hypothesis is stated in the form of the convolution integral in equation (1):

$$CM(x) = H(x) * W(x) \qquad (1)$$

For the demonstration of the spatial filter effect the following mathematical procedure was adopted A certain hypothetical function $H(x)$ was assumed and subjected to the convolution in equation (1). The shape of $H(x)$ was chosen so as to resemble excitation patterns likely to exist in reality The resulting hypothetical $CM(x)$ distribution was examined for properties similar to the ones found in the experimental data. In the event that a hypothetical $CM(x)$ closely approximated to a given real CM pattern it was further assumed that the corresponding hypothetical $H(x)$ approximated to the real hair-cell output pattern along the basilar membrane.

However according to equation (1) $CM(x)$ depends on $H(x)$ and the weighting function $W(x)$ and consequently it is important to use in the mathematical analysis a function $W(x)$ based on experimental observations. Fortunately useful data about $W(x)$ are available in the literature.

The weighting function $W(x)$

The electrical attenuation properties of the cochlear ducts in the guinea pig were studied by four different investigators or groups of investigators (von Békésy 1960 *a*; Tasaki & Fernández 1952; Tasaki et al., 1952; Misrahy et al. 1958; Johnstone et al. 1966). All investigators agree that the longitudinal spread of current in the basal turn can be accurately described by a core conductor model. In the apical parts of the cochlea complication arises due to the close packing of turns and possible alternative paths of cross-conduction between turns. Since in our experiments data were collected in the basal turn we only need to consider conditions there.

Von Békésy thoroughly investigated the spread of signals along the basal part of the cochlear partition over a length of 9 mm beginning at a distance of 0.5 mm from the basal end of the membrane. He used a set of paired electrodes placed oppositely in scala tympani and scala vestibuli along the first turn. A test signal was injected across the partition at one pair of electrodes and the resulting attenuated signal was measured at the other sensing electrode pairs. The signal attenuation he obtained amounted to 6 db per mm. Moreover he observed that there was no remarkable change in the attenuation along the partition whether measured in the apical or basal direction. Thus the signal attenuation for a generator pair of electrodes situated at a position x along the partition is symmetrical with respect to x. Von Békésy employed signals with frequencies ranging from 100 Hz to 2 kHz and he could not find any dependence of the attenuation value on signal frequency This indicates that the signal attenuation along the partition is predominantly due to the resistive properties of tissues and fluids and that the capacitive properties of the structures have negligible influence Tasaki & Fernández applied a d.c. signal across the partition in the basal turn and they also measured a decay of signal from the site of application of 6 db per mm. Von Békésy's extensive study well established the core conductor type of the electrical attenuation along the partition and we can formulate mathematically the attenuation or weighting function:

$$W(x) = e^{-\lambda|x|} \quad \lambda = \frac{1}{\theta} \qquad (6)$$

x and θ in mm. θ denotes the length constant or decay constant of the longitudinal signal attenuation. In the core conductor model θ takes the form

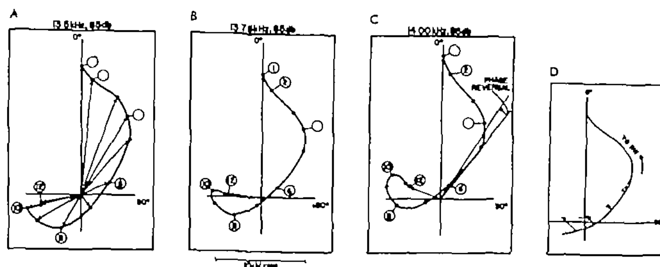

Fig 3.2 (A–C) Records (13.5 kHz, 13 75 kHz, 14 kHz) from Fig. 3 1.A redrawn in vector form. In (A) all output vectors are shown in (B) and (C) all vectors apart from 1 and 12 are omitted for clarity The trajectory connects all vector endpoints. Phase lag is counted in the clockwise direction. The trajectory approaches with increasing frequency the origin of the vector plane, note the concomitant increase in phase difference between 6 and 7 In (C) phase reversal occurs, 6 leading 5 in phase. In (A) and (B) the trajectory encircles the origin in (C) it does not.

(D) Artificially induced phase reversal by addition of small vector with large phase lag and amplitude which declines as the round window (*RW*) end of the array is approached.

phase lag (13 75 kHz) into one with phase reversal (14 kHz) This is illustrated in the schematic drawing of Fig. 3.2.D Let us add to all electrode outputs in a pattern like the one at 13 75 kHz a small vector with a large phase lag and a length which declines as the basal end of the array is approached. The resulting trajectory has an appearance like the one at 14 kHz, i e it does not encircle the origin Something analogous to this vector addition may be expected to happen in reality As the stimulus frequency is increased from 13 75 to 14 kHz the wavelengths in the excitation pattern will shorten and a small group of distant hair-cells will be operating with slightly larger phase lag than before The influence of these distant hair-cell outputs is of course felt with an amplitude which declines towards the basal end of the array The model provides a qualitative explanation for the observed phase reversal and it suggests the far reaching influence of alterations in the outputs of subsets of hair-cell operators on the appearance of the whole CM pattern an influence postulated by the spatial filter hypothesis.

A further point which deserves to be mentioned concerns the situation where the trajectory actually crosses the origin. This situation was thoroughly explored in a preparation where one electrode of the array recorded very nearly zero amplitude in the frequency region of the phase reversal. Thus this electrode output when plotted on the trajectory very nearly coincided with the origin of the vector plane. The output of this electrode was displayed on the oscilloscope screen and a faint sinusoidal signal was just noticeable in the background noise It was interesting to observe that the output signal was extremely unstable shifting abruptly back and forth by about 180 on the oscilloscope screen All other electrode outputs, however were perfectly stable This finding although it may seem strange at first glance can be interpreted quite plausibly Consideration of Fig 3 2 shows that the phase difference between the adjacent electrodes 6 and 7 grows continuously when the trajectory approaches the origin. When the trajectory crosses the origin this phase difference becomes approximately 180 Thus a point in the immediate vicinity of the origin, intermediate to 6 and 7 is framed by two vector bundles ap-

cochlea. We have to adapt this pattern to high frequencies in order to make the distribution CM(x) resulting from the spatial filter operation comparable to our high frequency records. We achieved this adaption by compressing the von Békésy pattern into a shorter length of membrane. With the further assumption that hair-cell output is directly proportional to the local mechanical stimulus we obtained a hypothetical hair-cell distribution $H(x)$.

With the functions $H(x)$ and $W(x)$ (see equation (6)) given we can execute the spatial filter operation. The convolution integral

$$\mathrm{CM}(x_0) = \int_{-\infty}^{\infty} H(x) \exp(-0.69|x_0 - x|)\, dx$$

was solved by graphical integration.

Thus the above formula, continuous in x was substituted by

$$\mathrm{CM}(x_0) = \frac{m-n}{s} \sum_{i=0}^{s} H(x_i) \exp(-0.69|x_0 - x_i|) \quad (8)$$

where

$$x_i = n + i\frac{m-n}{s} \quad i = 0, 1, \ldots, s$$

and

$$x_i, x_0 \in [n, m]$$

In equation (8) the limits of the integration interval $[-\infty, \infty]$ are replaced by the finite boundaries n, m. This is permissible provided the bulk of the pattern $H(x)$ lies within the interval $[n, m]$. For the graphical integration the interval $[n, m]$ was subdivided in $s = 10$ equal intervals.

Each $H(x_i)$ in equation (8) is characterized by an amplitude and a phase value and can therefore be represented as a vector. Thus for each x_0 ($x_0 \in [n, m]$) CM(x_0) forms the vector sum of the contributions $H(x_i)$ weighted by the appropriate attenuation factor. In Fig. 3.3 all functions involved in spatial filtering are shown. The graphical integration yields the

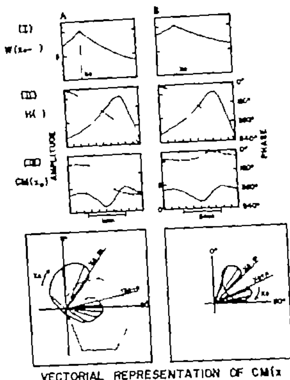

Fig. 3.3 Spatial Filtering of von Békésy pattern $H(x)$. In (A) $H(x)$ is compressed into interval $[n, m]$ = 2 mm. In (B), analogous to increase in frequency $[n, m]$ = 1 mm. All functions involved in spatial filtering are shown.

I. $W(x)$: weighting function, drawn for an arbitrary x_0. $W(x) = \exp(-0.69|x_0 - x|)$.

II. $H(x)$: hypothetical hair-cell output distribution of the von Békésy type.

III. CM(x_0): hypothetical CM distribution resulting from spatial filtering.

Bottom graph is the vector representation of CM(x_0). The convolution integral was solved by graphical integration, $[n, m]$ was subdivided into $s = 10$ equal intervals:

$$\mathrm{CM}(x_0) = \frac{m-n}{s} \sum_{i=0}^{s} H(x_i) \exp(-0.69|x_0 - x_i|);\ x_i, x_0 \in [n, m]$$

As an example it is shown in the vector plane in (A) how CM(x_0) forms the vector sum of the weighted contributions $H(x_i)$ for $x_0 =$ ( ). In the 'lower frequency' example (A) the trajectory encircles the origin of the vector plane, in the 'higher frequency' example (B) it does not. Note co-occurrence of amplitude minimum and large phase gradient in (A,III). ——, amplitude; - - -, phase.

pattern CM(x_0) in vector form and it can be seen in the vector plot in (A) how the weighted vectors $H(x_i)$ add up to CM(x_0) for $x_0 = n$ (see

$$\theta = \frac{1}{\sqrt{dR\,dG}} \tag{7}$$

where dR signifies the longitudinal resistance per unit length of the fluid filled canals and dG signifies the longitudinal conductance per unit length of the cochlear partition. Tasaki et al measured the resistances involved and calculated (see equation (7) and (6)) the attenuation along the partition They obtained a value of 6 db per mm They measured an electrical impedance across the cochlear partition of 100 to 200 Ω per cm in the basal turn at a frequency of 500 Hz. At 6 kHz they found an impedance about 15% less. Since this variation in impedance with frequency is very small compared to the variation of impedance at a single frequency (500 Hz) we may consider the attenuation independent of frequency This implies, of course that λ in equation (6) is considered a real quantity that is, neglecting capacitive effects of intracochlear structures.

Data considered so far concerned the attenuation of signals across the cochlear partition The result, unanimously achieved, gives an attenuation of 6 db per mm i.e. a decay constant $\theta = 1.45$ mm ($\lambda = 0.69$) However it needs to be clarified whether this value of θ is a good approximation to the real situation where the signal is generated by the hair cells within the organ of Corti presumably across the reticular lamina and not as in the above test cases across the cochlear partition It is likely that a pair of electrodes, the one electrode situated in scala media and the other in scala tympani, mimics the real situation better than does a pair of electrodes situated across the whole cochlear partition Experiments to explore the attenuation along the basilar membrane have been done with electrodes inserted into scala media and scala tympani

Misrahy et al measured the resistances involved in this latter situation and they calculated (using equation (7)) for the basal turn a decay constant $\theta = 1.18$ mm for the signal spread along the basilar membrane However Johnstone et al measuring the spread of current pulses along the membrane with electrodes in scala media, obtained an average length constant $\theta = 2$ mm in the first turn The discrepancy between these results is probably due to the fact that these experiments are extremely difficult to execute requiring utmost surgical cleanliness, a requirement not easy to meet when handling sets of recording electrodes. Taking the arithmetic mean of the two values gives a mean length constant $\theta_m = 1.59$ mm a value not significantly different from the length constant along the whole cochlear partition Thus for the mathematical operations in this thesis we used von Békésy's value for the length constant corresponding to a signal decay of 6 db per mm.

The weighting function in equation (6) takes into account the longitudinal spread of signal along the cochlear scalae It does not take account of the signal variation across the scalae. In accordance with the core conductor model we may neglect as a first approximation the effect of the distance between electrode tips and the basilar membrane on the CM distribution In Fig 2.11 A the CM pattern for the same stimulus parameter is shown measured at two different depths of insertion of the electrode array into scala tympani thus the distance between electrode tips and the basilar membrane was slightly different in the two records. There are only minor differences between the two patterns and we may therefore regard the potential variation across the scala tympani negligible as a first approximation.

Spatial filtering of hypothetical patterns $H(x)$

It is expedient to begin the mathematical analysis of the spatial filter effect by subjecting a function $H(x)$ to spatial filtering which has the shape of the mechanical excitation curves measured by von Békésy The highest stimulus frequency at which von Békésy observed the complete mechanical excitation pattern along the membrane was 300 Hz the pattern extended from about 19 mm to 29 mm along the basilar membrane of the human

cochlea. We have to adapt this pattern to high frequencies in order to make the distribution CM(x) resulting from the spatial filter operation comparable to our high frequency records. We achieved this adaption by compressing the von Békésy pattern into a shorter length of membrane. With the further assumption that hair-cell output is directly proportional to the local mechanical stimulus we obtained a hypothetical hair-cell distribution $H(x)$

With the functions $H(x)$ and $W(x)$ (see equation (6)) given we can execute the spatial filter operation. The convolution integral

$$CM(x_0) = \int_{-\infty}^{\infty} H(x) \exp(-0.69|x_0 - x|)\, dx$$

was solved by graphical integration.

Thus the above formula, continuous in x was substituted by

$$CM(x_0) = \frac{m-n}{s} \sum_i H(x_i) \exp(-0.69|x_0 - x_i|) \quad (8)$$

where

$$x_i = n + i\frac{m-n}{s} \quad i = 0, 1 \ldots s$$

and

$$x_i, x_0 \in [n, m]$$

In equation (8) the limits of the integration interval $[-\infty \; \infty]$ are replaced by the finite boundaries n m. This is permissible provided the bulk of the pattern $H(x)$ lies within the interval $[n \; m]$. For the graphical integration the interval $[n \; m]$ was subdivided in $s = 10$ equal intervals.

Each $H(x_i)$ in equation (8) is characterized by an amplitude and a phase value and can therefore be represented as a vector. Thus for each x_0 ($x_0 \in [n \; m]$) CM(x_0) forms the vector sum of the contributions $H(x_i)$ weighted by the appropriate attenuation factor. In Fig. 3.3 all functions involved in spatial filtering are shown. The graphical integration yields the

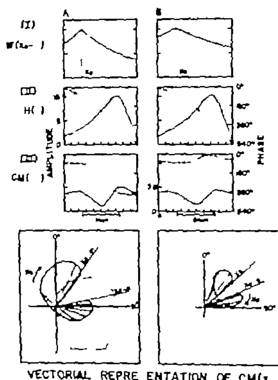

Fig. 3.3 Spatial Filtering of von Békésy pattern $H(x)$. In (A) $H(x)$ is compressed into interval $[n, m] = 2$ mm. In (B), analogous to increase in frequency $[n, m] = 1$ mm. All functions involved in spatial filtering are shown.

I $W(x)$: weighting function, drawn for an arbitrary x_0 $W(x) = \exp(-0.69|x_0 - x|)$.
II. $H(x)$: hypothetical hair-cell output distribution of the von Békésy type
III. CM(x_0): hypothetical CM distribution resulting from spatial filtering.

Bottom graph is the vector representation of CM(x_0). The convolution integral was solved by graphical integration; $[n, m]$ was subdivided into $s = 10$ equal intervals:

$$CM(x_0) = \frac{m-n}{s} \sum_{i=0} H(x_i) \exp(-0.69|x_0 - x_i|); x_i, x_0 \in [n, m]$$

As an example it is shown in the vector plane in (A) how CM(n) forms the vector sum of the weighted contributions $H(x_i)$ for $x_0 = n$ ( ). In the 'lower frequency' example (A) the trajectory encircles the origin of the vector plane, in the 'higher frequency' example (B) it does not. Note co-occurrence of amplitude minimum and large phase gradient in (A,III). —— amplitude; – – –, phase.

pattern CM(x_0) in vector form and it can be seen in the vector plot in (A) how the weighted vectors $H(x_i)$ add up to CM(x_0) for $x_0 = n$ (see

$$\theta = \frac{1}{\sqrt{dR\, dG}} \quad (7)$$

where dR signifies the longitudinal resistance per unit length of the fluid filled canals and dG signifies the longitudinal conductance per unit length of the cochlear partition Tasaki et al. measured the resistances involved and calculated (see equation (7) and (6)) the attenuation along the partition They obtained a value of 6 db per mm They measured an electrical impedance across the cochlear partition of 100 to 200 Ω per cm in the basal turn at a frequency of 500 Hz. At 6 kHz they found an impedance about 15% less. Since this variation in impedance with frequency is very small compared to the variation of impedance at a single frequency (500 Hz) we may consider the attenuation independent of frequency This implies, of course, that λ in equation (6) is considered a real quantity that is, neglecting capacitive effects of intracochlear structures.

Data considered so far concerned the attenuation of signals across the cochlear partition The result unanimously achieved gives an attenuation of 6 db per mm i e a decay constant $\theta = 1.45$ mm ($\lambda = 0.69$) However it needs to be clarified whether this value of θ is a good approximation to the real situation where the signal is generated by the hair cells within the organ of Corti presumably across the reticular lamina and not as in the above test cases across the cochlear partition. It is likely that a pair of electrodes, the one electrode situated in scala media and the other in scala tympani mimics the real situation better than does a pair of electrodes situated across the whole cochlear partition. Experiments to explore the attenuation along the basilar membrane have been done with electrodes inserted into scala media and scala tympani

Misrahy et al. measured the resistances involved in this latter situation and they calculated (using equation (7)) for the basal turn a decay constant $\theta = 1.18$ mm for the signal spread along the basilar membrane However Johnstone et al. measuring the spread of current pulses along the membrane with electrodes in scala media, obtained an average length constant $\theta = 2$ mm in the first turn The discrepancy between these results is probably due to the fact that these experiments are extremely difficult to execute requiring utmost surgical cleanliness, a requirement not easy to meet when handling sets of recording electrodes. Taking the arithmetic mean of the two values gives a mean length constant $\theta_m = 1.59$ mm a value not significantly different from the length constant along the whole cochlear partition Thus for the mathematical operations in this thesis we used von Békésy's value for the length constant corresponding to a signal decay of 6 db per mm

The weighting function in equation (6) takes into account the longitudinal spread of signal along the cochlear scalae it does not take account of the signal variation across the scalae In accordance with the core conductor model we may neglect as a first approximation the effect of the distance between electrode tips and the basilar membrane on the CM distribution In Fig 2.11 A the CM pattern for the same stimulus parameter is shown measured at two different depths of insertion of the electrode array into scala tympani thus the distance between electrode tips and the basilar membrane was slightly different in the two records. There are only minor differences between the two patterns and we may therefore regard the potential variation across the scala tympani negligible as a first approximation

Spatial filtering of hypothetical patterns $H(x)$

It is expedient to begin the mathematical analysis of the spatial filter effect by subjecting a function $H(x)$ to spatial filtering which has the shape of the mechanical excitation curves measured by von Békésy The highest stimulus frequency at which von Békésy observed the complete mechanical excitation pattern along the membrane was 300 Hz, the pattern extended from about 19 mm to 29 mm along the basilar membrane of the human

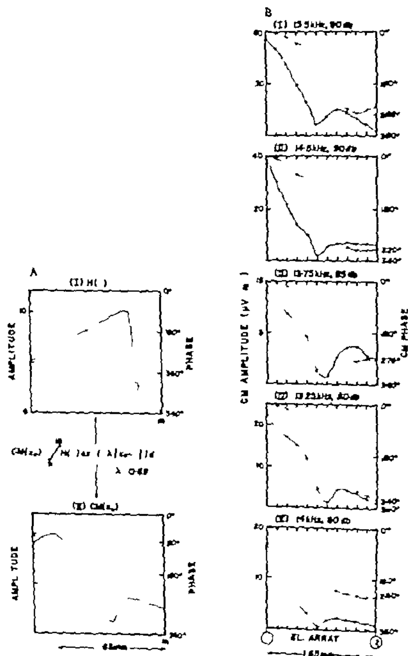

Fig. 3.5. (A.I–II) Hypothetical $H(x)$ and $CM(x_n)$ re-drawn from Fig. 3.4 B. Compare $CM(x_n)$ over the length 1.65 mm with experimental CM patterns in (B.I–V).

(B.I–V) Experimental CM amplitude and phase patterns obtained from five different guinea pigs. Stimulus parameters were essentially the same (stimulus frequency varied from 13.5 kHz to 14.5 kHz; SPL varied from 80 to 90 db). Note: Distinct amplitude minimum around 6 and 7; flat amplitude maximum around 8 and 9; large phase gradient in the region of amplitude minimum. On account of good quantitative agreement between $CM(x_n)$ (A.II) and experimental CM patterns (B.I–V) we assume $H(x)$ in (A.I) to be a close approximation—$H(x)^*$—to the real hair cell output patterns for the stimuli in (B.I–V), i.e. for stimulus frequencies between 13.5 and 14.5 kHz. ——, amplitude, - - - phase.

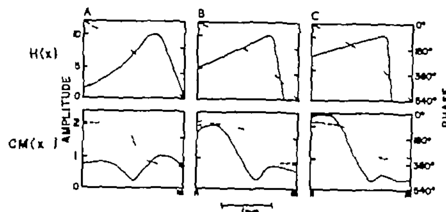

Fig. 3.4. Modification of 'von Békésy type' pattern $H(x)$. (A) $H(x)$ redrawn from Fig. 3.3.A. (B, C) Flattening the basal slope and steepening the apical slope of the envelope of $H(x)$ produces theoretical curves $CM(x_0)$ more similar to experimental CM patterns. —— amplitude ––– phase.

dashed line in vector diagram (A)). By plotting the amplitude and phase pattern of $CM(x_0)$ separately we obtain the hypothetical cochlear microphonic distribution $CM(x_0)$ in a fashion ready for comparison with experimental patterns.

In Fig. 3.3.A $H(x)$ was compressed into an interval length of 2 mm while in (B) analogous to an increase in frequency the interval length was only 1 mm. Let us call A the 'lower frequency' and B the 'higher frequency' example.

Practically all significant features of the resulting patterns $CM(x_0)$ are consistent with experimental findings. The amplitude of $CM(x_0)$ in the 'higher frequency' case is smaller than in the 'lower frequency' case; this is compatible with real patterns which showed an overall drop in amplitude with increasing stimulus frequency. The overall phase variation along the space coordinate in the 'higher frequency' example is very small, a feature well shown by the experimental patterns in Fig. 3.1.A at high stimulus frequencies. In the 'low frequency' example there is progressive phase lag along x_0, thus the trajectory in the vector representation encircles the origin of the vector plane. In the high frequency example no encirclement of the origin occurs and the phase pattern shows phase reversal, the more apical part of the pattern leading in phase the more basal part. The occurrence of phase reversal with increase in stimulus frequency was one of the main characteristics of experimental CM patterns. In the 'lower frequency' example we observe the co-occurrence of an amplitude minimum and a large phase gradient. This also was a main characteristic of experimental CM patterns.

Thus it is demonstrated that all salient features of the measured CM patterns can be qualitatively reproduced by spatially filtering an excitation pattern of the 'von Békésy type'. It should be noted that $CM(x_0)$ at a particular point x_0 does not reflect the hair-cell output at this point x_0; this can be clearly seen in Fig. 3.3. Thus the notion held by several investigators that an electrode records local hair-cell activity is proved incorrect.

Quantitative comparison between theoretical and experimental CM patterns

In the foregoing section we showed the excellent qualitative agreement between theoretical CM patterns deducible from the 'von Békésy type' function $H(x)$ and our own experimental data. Yet, closer inspection of the theoretical curves $CM(x_0)$ in Fig. 3.3 reveals that the quantitative agreement with measured patterns is rather poor; this applies especially to the shape of the amplitude pattern of $CM(x_0)$ which shows a large distant maximum.

We attempted to improve the quantitative fit between the theoretical and measured CM patterns by systematically modifying the shape of the hypothetical pattern $H(x)$. Since $H(x)$ consists of two parameter distributions, those of amplitude and phase, we can manipulate either or both of the two functions. Due to the lack

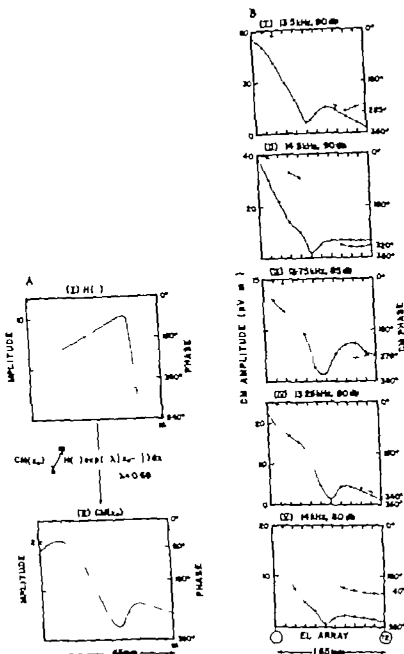

Fig. 3.5. (A.I, II) Hypothetical $H(x)$ and $CM(x_0)$ redrawn from Fig. 3.4 B. Compare $CM(x_0)$ over the length 1.65 mm with experimental CM patterns in (B.I–V).

(B.I–V) Experimental CM amplitude and phase patterns obtained from five different guinea pigs. Stimulus parameters were essentially the same (stimulus frequency varied from 13.5 kHz to 14.5 kHz, SPL varied from 80 to 90 db). Note: Distinct amplitude minimum around 6 and 7, flat amplitude maximum around 8 and 9, large phase gradient in the region of amplitude minimum. On account of good quantitative agreement between $CM(x_0)$ (A.II) and experimental CM patterns (B.I–V) we assume $H(\ )$ in (A.I) to be a close approximation—$H(x)^*$—to the real hair cell output patterns for the stimuli in (B.I–V), i.e. for stimulus frequencies between 13.5 and 14.5 kHz. ——, amplitude, – – phase.

In Fig. 3 3.A $H(x)$ was compressed into an interval length of 2 mm while in (B) analogous to an increase in frequency the interval length was only 1 mm Let us call A the lower frequency' and B the higher frequency' ex ample

Practically all significant features of the re sulting patterns $CM(x_0)$ are consistent with ex perimental findings. The amplitude of $CM(x_0)$ in the higher frequency' case is smaller than in the lower frequency case this is compa tible with real patterns which showed an over all drop in amplitude with increasing stimulus frequency The overall phase variation along the space coordinate in the higher frequency example is very small a feature well shown by the experimental patterns in Fig 3 1 A at high stimulus frequencies. In the low fre quency' example there is progressive phase lag along x_0, thus the trajectory in the vector re presentation encircles the origin of the vector plane In the high frequency' example no en circlement of the origin occurs and the phase pattern shows phase reversal, the more apical part of the pattern leading in phase the more basal part. The occurrence of phase reversal with increase in stimulus frequency was one of the main characteristics of experimental CM patterns. In the lower frequency' example we observe the co-occurrence of an am minimum and a large phase gradient. Th was a main characteristic of experiment patterns.

Thus it is demonstrated that all salie tures of the measured CM patterns c qualitatively reproduced by spatially fil an excitation pattern of the 'von Békésy It should be noted that $CM(x_0)$ at a part point x_0 does not reflect the hair-cell c at this point x_0 this can be clearly seen i 3.3 Thus the notion held by several in gators that an electrode records local ha activity is proved incorrect.

Quantitative comparison between theoret and experimental CM patterns

In the foregoing section we showed th cellent qualitative agreement between retical CM patterns deducible from the Békésy type function $H(x)$ and our ow perimental data. Yet, closer inspection o theoretical curves $CM(x_0)$ in Fig 3.3 re that the quantitative agreement with mea patterns is rather poor this applies espe to the shape of the amplitude patte $CM(x_0)$ which shows a large distant maxi

We attempted to improve the quantitati between the theoretical and measured CM terns by systematically modifying the sha the hypothetical pattern $H(x)$ Since $H(x)$ sists of two parameter distributions, thos amplitude and phase we can manipulate ei or both of the two functions. Due to the l

"H(x)" and the frequency response curve

We obtained from the considerations outlined in the previous section a distribution $H(x)$" representing the approximate shape of the hair cell activity pattern along the membrane at stimulus frequencies from 13.5 kHz to 14.5 kHz. We are now in the position to compare this information about the excitation pattern with the data available from mechanical measurements. However $H(x)$ is a distribution along the space variable x while all the mechanical data are frequency response curves of points along the membrane, i.e. they are functions of the frequency variable. For the comparison between the two sets of data we have to deduce from the shape of $H(x)$" the corresponding frequency response curve. This deduction can be done provided we know the conversion formula relating the space variable x to the stimulus frequency f in the guinea pig's cochlea.

Greenwood (1961) formulated the connection between stimulus frequency and the location of the maximum displacement along the basilar membrane in the guinea pig. He used the expression.

$$f = A(10^{a[illegible]} - 1) \qquad (9a)$$

where f denotes stimulus frequency in Hz and [illegible] denotes the distance in mm of the maximum displacement from the apical end of the membrane. In this thesis we measured the spatial coordinate x from the basal end of the membrane. In the guinea pig the basilar membrane has a total length of 18.5 mm. Thus by using the substitution

$$r = 18.5 - x$$

we can write equation (9 a) in the form.

$$f = A(10^{[illegible]} - 1) \qquad (9b)$$

Greenwood determined the values ([illegible]) by fitting the function (9 a) to von Békésy's mechanical data measured in the upper turns of the cochlea. He obtained two sets of values, the one set giving rise to function G

K. The position of the electrode array relative to the space coordinate is shown. M indicates the position of the envelope maximum of $H(x)$" according to Fig. 3.5. M falls into the region between electrodes 8 and 9. With M and the stimulus frequencies (13.5 kHz to 14.5 kHz) given for which $H(x)$" is considered an approximation to the hair-cell output distribution we can plot our results into the graph. They are marked K and they show good agreement with G

$$G_1 \quad f = 166.2(10^{[illegible]} - 1)$$

the other set leading to G_2,

$$G_2 \quad f = 253(10^{[illegible]} - 1)$$

Both functions G_1 and G_2 are shown in Fig. 3.7. The function G_2 fits the low frequency

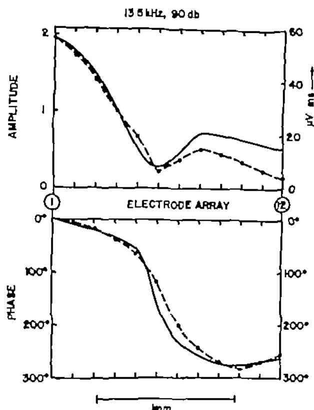

Fig 3.6 Hypothetical CM(x_0) from Fig. 3 4 B and Fig. 3.5.A.II drawn together with experimental CM pattern from Fig. 3.5.B I The relative amplitude for CM(x_0) is indicated on the left hand scale the amplitude for the experimental 13.5 kHz, 90 db pattern is indicated on the right hand scale in μV rms. Both amplitude and phase patterns show good quantitative agreement. —— hypothetical CM(x_0) - - - measured CM pattern at 13.5 kHz, 90 db.

of experimental data on the longitudinal phase variation in the mechanical excitation pattern at frequencies beyond 300 Hz we left the phase pattern of $H(x)$ unchanged. The amplitude envelope of $H(x)$ was modified and the corresponding CM(x_0) was calculated by graphical integration according to equation (8)

In Fig 3 4 the result of this procedure is shown Fig 3 4 A displays the 'von Békésy type pattern $H(x)$ used in Fig 3.3 A It can be seen that flattening the basal slope and steepening the apical slope of the envelope of $H(x)$ produces CM(x_0) patterns which approximate in shape very closely to experimental CM patterns. The CM(x_0) in Fig 3 4 B gives the closest fit and it is redrawn in Fig. 3.5 A together with experimental CM distributions.

It can be seen at once that there is very g agreement between the hypothetical CM in Fig. 3.5 A II and the measured CM patt in Fig 3 5 B I to V The experimental patt were obtained from five different guinea p The stimulus parameters in all five cases w essentially the same thus the stimulus quency varied only from 13.5 kHz to 14.5 k and the stimulus intensity varied from 80 90 db SPL. All experimental amplitude p terns exhibit a distinct minimum around el trodes 6 and 7 and a flat maximum arou electrodes 8 and 9 In the region of the am tude minimum all patterns show the char teristic large phase variation The overall ph change along the array amounts in the f cases to 285 320 276 350 240 resp tively For the comparison between the th retical and experimental CM patterns, we co sider the theoretical pattern over a length 1 65 mm equal to the width of the electr array The overall phase variation in t length interval of the theoretical curve has value of 280 Undoubtedly there is very go quantitative agreement between the theoreti and experimental curves.

In order to show the quantitative fit mo clearly the measured CM pattern of Fig 3.5 E was redrawn along with the theoretical patte of Fig. 3.5 A.II in the same diagram in Fi 3 6 The excellent agreement between t hypothetical and the measured CM patter well documented in Fig 3 6 suggests the fo lowing logical conclusion the hypothetical pa tern $H(x)$ from which the hypothetical CM(x in Fig 3 6 was deduced must approximate ve closely to the real hair-cell output patter which produced the measured CM distribu tion in Fig 3 6

Thus in the following discussion we shall a sume that the hair-cell output pattern at stimu lus frequencies from 13.5 kHz to 14.5 kHz ca be represented by the hypothetical patter "$H(x)$" given in Fig 3.5 A.I (Writing $H($ with inverted commas indicates that "$H(x)$" i considered to be an approximation to the rea curve)

"H(x)" and the frequency response curve

We obtained from the considerations outlined in the previous section a distribution "$H(x)$" representing the approximate shape of the hair cell activity pattern along the membrane at stimulus frequencies from 13.5 kHz to 14.5 kHz. We are now in the position to compare this information about the excitation pattern with the data available from mechanical measurements. However $H(x)$ is a distribution along the space variable x while all the mechanical data are frequency response curves of points along the membrane, i.e. they are functions of the frequency variable. For the comparison between the two sets of data we have to deduce from the shape of "$H(x)$" the corresponding frequency response curve. This deduction can be done provided we know the conversion formula relating the space variable x to the stimulus frequency f in the guinea pig's cochlea.

Greenwood (1961) formulated the connection between stimulus frequency and the location of the maximum displacement along the basilar membrane in the guinea pig. He used the expression.

$$f = A(10^{ar} - 1) \qquad (9\,a)$$

where f denotes stimulus frequency in Hz and r denotes the distance in mm of the maximum displacement from the apical end of the membrane. In this thesis we measured the spatial coordinate x from the basal end of the membrane. In the guinea pig the basilar membrane has a total length of 18.5 mm. Thus by using the substitution

$$r = 18.5 - x$$

we can write equation (9 a) in the form.

$$f = A(10^{a(18.5-x)} - 1) \qquad (9\,b)$$

Greenwood determined the values (A, a) by fitting the function (9 a) to von Békésy's mechanical data measured in the upper turns of the cochlea. He obtained two sets of values, the one set giving rise to function G_1

$$G_1: f = 166.2(10^{[illegible](18.5-x)} - 1)$$

the other set leading to G_2,

$$G_2: f = 253(10^{[illegible](18.5-x)} - 1)$$

Both functions G_1 and G_2 are shown in Fig. 3.7. The function G_2 fits the low frequency

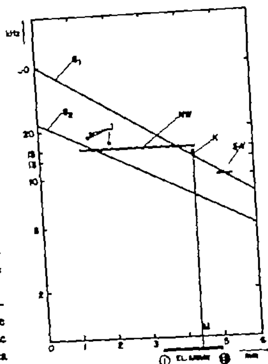

Fig. 3.7. Stimulus frequency on logarithmic scale plotted versus locus of maximum displacement along the guinea pig's basilar membrane. The space coordinate is measured from the basal end of the membrane, it is given in mm.

G_1 and G_2: Greenwood's functions.

SW: Damage of organ of Corti after overstimulation with 10 kHz tone, observed by Smith & Wever (1949).

M falls into the region between electrodes 8 and 9. With M and the stimulus frequencies (13.5 kHz to 14.5 kHz) given for which "$H(x)$" is considered an approximation to the hair-cell output distribution we can plot our results into the graph. They are marked K and they show good agreement with G.

Fig. 18. Detail (enlargement) of Fig. 17. 100 000.

for the enzyme if penetration of the substrate and of the lead salt is possible. Recent studies indicate that the enzymes are active inside the lysosomes (De Duve, 1970). The first sign of a pathological process is the occurrence of a positive enzyme reaction as well as incipient intracellular lysis. It is as if the lysosomes—for reasons still unknown—start growing and that the permeability of their membrane alters in a way so that the hydrolases can get into contact with the surrounding cytoplasm. At this stage electron microscopy shows small, round, empty vesicles exhibiting centrally a positive reaction with lead deposits surrounded by a small lytic zone. From then on the development will be very rapid. The lytic zones grow in size and number. In a few cases we have been able to visualize the exocytosis of the hydrolases, a large vesicle opening into the surrounding tissue where incipient destruction is taking place (Fig. 2). Without a doubt this process will, despite the exocytosis phenomenon, also destroy the cell itself. The destruction soon gives rise to swelling of the mitochondria which lose their crests. In this way the mitochondria may give a positive enzyme reaction, meaning that no further active oxidation enzymes are left (Figs. 17, 18). Vesicular degeneration of the cell will occur rapidly, the entire cytoplasm getting vesicular. The nucleus itself also undergoes lysis, and the result soon becomes a "ghost cell" (Figs. 4, 19). At this stage, it is difficult

Fig 19 Extensive cytoplasmatic lysis with clear-cut enzymatic activity 19 000

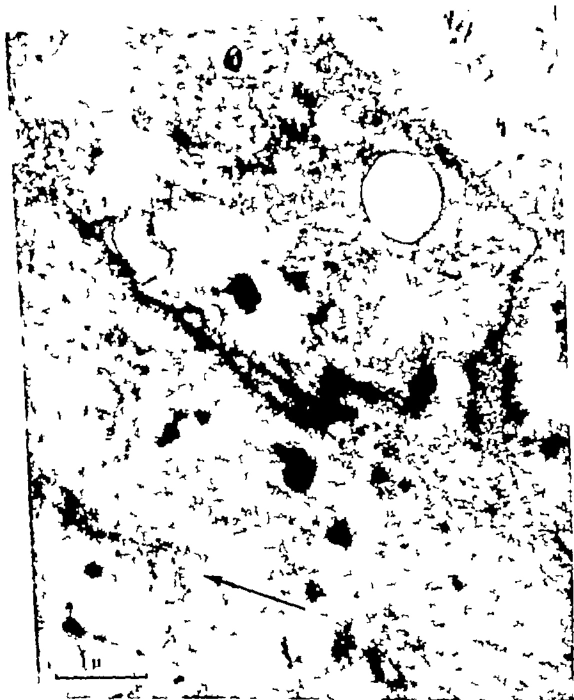

Fig. 70. Active enzymatic process around the cell lacuna and the canaliculi. 30 000

Fig 19 Extensive cytoplasmatic lysis with clear-cut enzymatic activity 19 000

activity which they designated *osteolysis* (or osteocytic resorption). This process involves, at the same time, rapid maturation of osteocytes and changes in the surrounding bony matrix, so that at this site there is a low concentration of mineral as well as of metachromatic organic material consisting of mucopolysaccharides staining with PAS. This is presumably approximately the same mechanism which we observed in the destructive phase of otosclerosis.

Recently it was demonstrated by Andersen et al. (1969), on the basis of studies on the growth of the otic capsule in the human foetus, that at an early stage of foetal life the cavities in the otic capsule are formed by histiocytes possessing the ability for chondrolysis.

The teory on osteoclastic resorption, then, cannot answer all the questions posed by recent studies.

During the past 10 years, the electron microscope has made it possible despite great technical difficulties to determine the sub-microscopic structure of the osteocytes. Especially Baud (1962, 1968) and Bélanger et al. (1963 1965) have supplied the morphological basis for investigating the physiological role played by these cells.

Several authors (Ruyter 1964 Manning & Butler 1965 Baud, 1968) have demonstrated the presence of lysosome-like bodies in the osteocytes by the histochemical demonstration of acid phosphatase activity in the osteocytes.

Other lysosomal hydrolytic enzymes capable of digesting proteins (Bélanger & Migiocovsky 1963 Woods & Nichols, 1965) as well as mucopolysaccharides (Schlager 1959 Gubisch & Schlager 1961) are also present and may ensure the attack upon organic bone matrix.

As far as bone resorption is concerned the possible role of lysosomes and, incidentally the value of acid phosphatase activity has been studied by Scott & Pease (1956), Gonzales & Karnovsky (1961), and Hancox & Boothroyd (1961) Woods & Nichols (1965) found some fractions of rat bones to be rich in collagenase activity Goldhaber (1961) demonstrated that resorption of bone was followed by degradation of bone collagen. One or several enzymes are released during the resorption of bone (Stern, 1965), and this or these enzymes have collagenolytic activity The studies of Kaufman et al. (1965) confirmed that active resorption of bone in tissue cultures is followed by a release of a collagenolytic factor capable of breaking down collagen fibrils at a neutral pH and 37 C. This process has been found to be increased by parathyroid extract (Walker et al., 1964) and heparin.

The disagreement between the osteoclastic resorption theory and the enzyme theory which we are advancing here—and which can explain our light microscopic as well as electron microscopic findings—is perhaps more apparent than real. It is known that when the osteoclasts act locally through their ruffled borders and absorb calcium hydroxyapatite crystals by pinocytosis, they may also exert an important acid phosphatase activity (Schajowicz & Cabrini, 1958 Burstone 1959 1962 Handelman et al., 1964), an activity which perhaps plays a role at a certain distance from the cell, although this has never been demonstrated.

The enzymatic lysosomal theory we are advancing is based upon morphological as well as experimental findings. Morphologically as previously mentioned, the *regular centrifugal* extension of large destruction foci (in the way of a "front") as well as the findings of small *foci "splashing* around can only be explained by an enzymatic process. The presence of cells showing in their cytoplasm a varying number of lysosomal, dense bodies, and which we have called histiocytes (although names are not the cardinal point) guarantee the enzymatic material needed for the bone resorption. The activity of the numerous hydrolytic enzymes found in the lysosomes explains—by reason of the protease, hyaluronidase, cathepsin, and acid phosphatase content—why destruction of the tissue may take place, although it is, as in this case, a dense bony tissue with abundant collagen. In addition, we have demonstrated the extension of cell destruction caused by changes in the permea-

to follow the localization of the enzyme, as it diffuses into the lacuna, the canaliculi, and the surrounding tissue. However despite advanced lysis, we have in a few cases been able to find occasional apparently intact lysosomes in the focus.

9 Discussion

In the present study we have tried to place otosclerosis research on a cellular basis Thereby we have attempted to throw some light upon the problem relating to the lytic phase of the otosclerotic process.

The course of the disease cannot be divided, clearly and simply into two successive phases, a destructive and a rebuilding one It runs a long course during which the changes do not automatically follow upon each other There is no doubt that quiet phases occur between two acute ones. In addition destructive and rebuilding phases may be observed at the same time in neighbouring foci However the destructive or lytic phase is always the first one, so that it is invariably present at the onset of the disease As pointed out in the section on the biochemistry of bone formation, it is presumably in this phase that the cellular mechanism is most difficult to understand

Claiming that it is a classical fact that osteoclasts alone are responsible for the destruction is presumably not entirely true No doubt osteoclasts play a decisive role in the resorption and remodelling of *normal* long bones On the other hand it is by no means certain that they play a role in all *abnormal* processes of bone resorption We have previously discussed the relative *absence of osteoclasts in active otosclerotic* foci To elucidate the occurrence of osteoclasts in the otosclerotic focus we studied 84 foci in 56 otosclerotic temporal bones in the light microscope. 30 of these foci proved to be highly active 32 of moderate activity and 22 inactive No osteoclasts were demonstrable in any specimen from foci that showed no or moderate activity (a total of 54) Of the 30 foci with high activity 6 were found to contain many osteoclasts, 8 scattered, and 3 occasional osteoclasts. Thirteen highly active foci were found to be entirely devoid of osteoclasts We have noticed also that the osteoclasts, when present, are almost invariably in the centre of the focus where brisk remodelling of newformed bony tissue takes place On the other hand we could not demonstrate osteoclasts in the marginal area of the focus where resorption of the original labyrinthine capsule takes place.

In addition, the precise and constant morphological electron microscopic findings in the extension zone of the active focus do not agree with the classical theory on osteoclastic resorption When actively engaged in a process of bone resorption, the osteoclasts generally make deep irregular encroachments into the bony tissue which is being destroyed Our regular finding of a distinct, well-defined "front" indicates that there can be no question of such a *destruction under these conditions Furthermore*, it is difficult to explain how microfoci also a constant finding, may be present in the tissue which is still normal and at some distance from the focus, if osteoclasts were the only cause of bone resorption in the otosclerotic focus

Osteoclasts need not be the only cause of bone resorption Various authors have suggested that the osteocytes may be capable of limited resorption of their lacunar walls (Heller Steinberg. *1951 Kind 1951) Especially after treat*ment with parathyroid extract (Heller Steinberg 1951 Jowsey 1960 Talmage 1962) osteocytes have been shown to take part in bone resorption However it was Bélanger and his coworkers (1963 1965) who described a specific form of bone resorption related to osteocytic

activity which they designated *osteolysis* (or osteocytic resorption) This process involves, at the same time, rapid maturation of osteocytes and changes in the surrounding bony matrix, so that at this site there is a low concentration of mineral as well as of metachromatic organic material consisting of mucopolysaccharides staining with PAS This is presumably approximately the same mechanism which we observed in the destructive phase of otosclerosis.

Recently it was demonstrated by Andersen et al. (1969), on the basis of studies on the growth of the otic capsule in the human foetus, that at an early stage of foetal life the cavities in the otic capsule are formed by histiocytes possessing the ability for chondrolysis.

The teory on osteoclastic resorption, then, cannot answer all the questions posed by recent studies.

During the past 10 years, the electron microscope has made it possible, despite great technical difficulties, to determine the sub-microscopic structure of the osteocytes. Especially Baud (1962, 1968) and Bélanger et al. (1963 1965) have supplied the morphological basis for investigating the physiological role played by these cells.

Several authors (Ruyter 1964 Manning & Butler 1965 Baud, 1968) have demonstrated the presence of lysosome-like bodies in the osteocytes by the histochemical demonstration of acid phosphatase activity in the osteocytes.

Other lysosomal hydrolytic enzymes capable of digesting proteins (Bélanger & Migicovsky 1963 Woods & Nichols, 1965) as well as mucopolysaccharides (Schlager 1959 Gubetch & Schlager 1961) are also present and may ensure the attack upon organic bone matrix.

As far as bone resorption is concerned, the possible role of lysosomes and, incidentally the value of acid phosphatase activity has been studied by Scott & Pease (1956), Gonzales & Karnovsky (1961), and Hancox & Boothroyd (1961) Woods & Nichols (1965) found some fractions of rat bones to be rich in collagenase activity Goldhaber (1961) demonstrated that resorption of bone was followed by degradation of bone collagen. One or several enzymes are released during the resorption of bone (Stern, 1965) and this or these enzymes have collagenolytic activity The studies of Kaufman et al (1965) confirmed that active resorption of bone in tissue cultures is followed by a release of a collagenolytic factor capable of breaking down collagen fibrils at a neutral pH and 37 C. This process has been found to be increased by parathyroid extract (Walker et al., 1964) and heparin.

The disagreement between the osteoclastic resorption theory and the enzyme theory which we are advancing here—and which can explain our light microscopic as well as electron microscopic findings—is perhaps more apparent than real. It is known that when the osteoclasts act locally through their ruffled borders and absorb calcium hydroxyapatite crystals by pinocytosis, they may also exert an important acid phosphatase activity (Schajowicz & Cabrini, 1958 Burstone 1959 1962 Handelman et al 1964) an activity which perhaps plays a role at a certain distance from the cell, although this has never been demonstrated.

The enzymatic lysosomal theory we are advancing is based upon morphological as well as experimental findings. Morphologically as previously mentioned, the regular centrifugal extension of large destruction foci (in the way of a front") as well as the findings of small foci splashing" around can only be explained by an enzymatic process. The presence of cells showing in their cytoplasm a varying number of lysosomal, dense bodies, and which we have called histiocytes (although names are not the cardinal point) guarantee the enzymatic material needed for the bone resorption. The activity of the numerous hydrolytic enzymes found in the lysosomes explains—by reason of the protease, hyaluronidase, cathepsin, and acid phosphatase content—why destruction of the tissue may take place, although it is, as in this case, a dense bony tissue with abundant collagen. In addition, we have demonstrated the extension of cell destruction caused by changes in the permea-

bility of the lysosomal membrane Extrusion of material, or right out cell destruction will in both events release hydrolytic material When the activity of the acid phosphatases is used as a cytochemical index, this hydrolytic material has proved to be active both within the cell, immediately around the cell lacuna, in the extension of the focus, and in microfoci In this way the enzymatic theory can explain the destruction, its special course and the extension process

Thus, we have brought otosclerosis research on a cellular basis Thereby we can correlate the pathological condition to a number of important *in vitro* studies of embryonic bone and cartilage cells For instance, it has been reported by Sledge (1965) and by Vaes (1964 1965) that under different conditions, such as an increase in the oxygen tension to the cells or administration of parathyroid hormone, the hydrolytic lysosomal activity will increase and result in resorption of the culture On the basis of our morphological and experimental studies we believe that this is what happens in the otosclerotic focus. During the lytic phase irrespective of its cause—be it e g. pregnancy inflammation, traumas, irradiation, etc —the *lysosomal hydrolyses make up a common* denominator in the otosclerotic resorption.

10 Summary in French

Les auteurs soulignent dans leur introduction l'énorme fossé qui sépare actuellement les remarquables résultats du traitement chirurgical de l'ignorance qui caractérise encore la compréhension biologique de l'otospongiose Ils insistent sur la nécessité d'une étroite collaboration entre chirurgiens et chercheurs qui seule permet de placer l'étude de la maladie otospongieuse sur un plan véritablement biologique c'est à-dire cellulaire et enzymatique

Dans un deuxième chapitre sont résumés les études biochimiques et histochimiques concernant la maladie Les auteurs indiquant que les études biochimiques portant sur l'analyse des fluides organiques, les dosagen hormonaux etc n'ont jusqu'ici fourni que des résultats assez contradictoires par contre les résultats des rares études histochimiques sont plus cohérents et concordent pour assigner un rôle de premier ordre aux mucopolysaccharides et au collagène de même qu'ils s'accordent pour reconnaître au niveau de foyer otospongieux une augmentation des enzymes respiratoires et des activités phosphatisiques alcalines et acides.

Le troisième chapitre est consacré à un résumé de nos connaissances actuelles concernant le rôle des phosphatases dans le processus complexe de l'ossification et de la destruction du tissu osseux, processus que l'on retrouve tout au long de la longue évolution de l'otospongiose

Puis les auteurs fournissent des précisions sur leur matériel et les techniques utilisées. Ils ont étudié 14 « lamelles ostéoïdes » et 50 fragments osseux d'étriers, tous fixés immédiatement après leur prélèvement chirurgical (fixation classique par la glutaraldehyde à 2% en tampon cacodylate 0 1 M) La décalcification lorsqu'elle s'avérait nécessaire fut effectuée en 12 h à froid dans une solution d'EDTA à 4,5 % de façon à ce que l'osmolarité de toutes les solutions soient situées aux environs de 440 millosmoles

La recherche enzymatique (phosphatase acide) est effectuée suivant la technique de Gomori légèrement modifiée puis une post fixation osmique est pratiquée Les coupes obtenues après section furent colorées uniquement à l'acétate d'uranyl Les résultats observés peuvent être résumés ainsi

Durant la phase destructive ou de lyse la microscopie électronique révèle des foyers extensifs, sans doute provoqués par la coalescence de plusieurs zones de lyse Ces foyers sont

caractérisés par leurs bords nettement tranchés, par l'existence très fréquente en leur voisinage immédiat de microfoyers dont la taille ne dépasse pas quelques microns et qui semblent bien précéder le front d'extension de la maladie. En outre, lorsque la destruction tissulaire est encore en cours, un aspect très caractéristique est réalisé par l'effilement et la perte de striation caractéristique des très nombreuses fibres collagènes de l'os, les auteurs le décrivent sous le nom d'aspect en « pipette Pasteur

L'aspect des cellules est discuté. En particulier les auteurs soulignent le fait que certains ostéocytes sans être touchés par le processus otospongieux offrent des aspects dégénératifs qui font partie des aspects métaboliques normaux de la capsule otique

En outre au sein des foyers de lyse on trouve des cellules auxquelles on attribue une valeur histiocytaire. Ces cellules semblent jouer dans le processus de lyse un rôle plus important que les ostéoclastes qui sont classiquement tenus pour responsables des processus de destruction. Une caractéristique capitale de ces cellules est leur richesse en lysosomes. La valeur physiologique de ces vésicules limitées par une seule membrane dont le contenu est dense aux électrons est maintenant connue On leur attribue essentiellement un rôle de stockage des principales enzymes hydrolytiques de même qu'un rôle de digestion des corps étrangers et molécules phagocytées. Il résultate de ces données que la rupture de leur membrane peut provoquer la destruction des tissus péricellulaire ainsi qu'éventuellement la mort de la cellule. Les mêmes constatations cytologiques furent effectuées au niveau des lamelles ostéoïdes de Causse qui apparaissent comme des foyers d'os otospongieux en situation intramuqueuse et juxta focales.

La théorie enzymatique proposée par les auteurs et qui fait des lysosomes l'élément principal de la phase destructive de l'otospongiose a été confirmée par la recherche de l'activité phosphatasique acide au niveau du foyer otospongieux, on reconnaît en effet très généralement à cette enzyme une valeur d'index des différentes activités hydrolytiques normalement contenues dans les lysosomes

Les auteurs ont mis en évidence au microscope électronique une activité phosphatasique acide en des localisations très précises de l'os otospongieux.

1 — au niveau d'ostéocytes ou d'histiocytes en voie de destruction (en particulier au niveau des zone de lyse intracytoplasmique consécutives à la rupture des vésicules lysosomales)

2. — au niveau des logettes cellulaires et des canalicules qui en partent.

3 — au niveau de front d'extension des foyers otospongieux actifs (l'étroite bande d'activité enzymatique mordant toujours sur le tissu normal)

4 — au sein des microfoyers qui précèdent le front d'extension

En conclusion

Les auteurs proposent pour expliquer la phase de lyse du foyer otospongieux, la moins bien connue sans aucun doute une théorie enzymatique qui fait appel à l'activité hydrolytique du contenu des lysosomes. Cette théorie explique parfaitement les constatations morphologiques tirées de l'étude électronmicroscopique et qui caractérisent cette phase de lyse.

11 Summary in German

Die Verfasser unterstreichen in der Einleitung ihrer Veröffentlichung die *enorme Kluft*, die zur Zeit zwischen den bemerkenswerten Ergebnissen der operativen Behandlung der Otospongiose und der Unkenntnis, die noch das biologische Verständnis dieser *Krankheit* charakterisiert, besteht. Sie legen Nachdruck auf die Notwendigkeit einer engen Zusammenarbeit zwischen Chirurgen und Forschern allein eine solche erlaubt es, die Untersuchungen dieses

Leidens auf ein echt biologisches, d h ein zell und enzymatisches Gebiet zu leiten

Im zweiten Abschnitt werden die bio- und histochemischen Studien dieser Krankheit zu sammengefasst Die Verfasser weisen darauf hin, dass die biochemischen Untersuchungen, die die Analyse der organischen Flüssigkeiten die Hormonbestimmungen usw betreffen, bis jetzt nur ziemlich widersprechende Ergebnisse lieferten Im Gegensatz dazu zeigen die raren histochemischen Resultate besseren Zusammen hang und stimmen darin überein den Muko-polysacchariden und Kollagenen eine Rolle er sten Ranges einzuräumen, ebenso wie sie sich einig sind um im Bezirke des otospongiosen Krankheitsherdes eine Zunahme der Atmungs-fermente und der alkalischen und sauren Phos phatase-Aktivitäten zu erkennen

Das dritte Kapitel ist eine Zusammenfassung der heutigen Kenntnisse in der Bedeutung der Phosphatasen für den komplexen Verlauf der Ossifikation und der Destruktion der Knochen gewebe, diesen Prozess findet man im Laufe der ganzen, langen Entwicklung der Otospongi ose wieder

Anschliessend legen die Verfasser Angaben über ihr Material und die angewandten Tech niken vor Sie haben 14 „Osteoidplättchen und 50 vom Steigbügel herrührende Knochenstück chen untersucht alle waren sofort nach der operativen Entfernung fixiert worden (übliche Fixierung mit 2%ig. Glutaraldehyd — als Puf fer Kakodylate 0 1 M) Wenn eine Entkalkung nötig war wurde sie in kaltem Zustand in einer 4,5% igen EDTA Lösung vorgenommen (12 Stunden) sodass das isotonische Gleichgewicht aller Lösungen ungefähr bei 440 mOsmol lag.

Die enzymatische Untersuchung (saure Phos-phatase) wurde mit Hilfe der Gomori Methode durchgeführt, die eine leichte Abänderung er fahren hatte anschliessend wurde eine Nach fixierung mit Osmiumsäure vorgenommen. Die gewonnenen Schnitte wurden nur mit Uranyl acetat gefärbt

Die gesammelten Erfahrungen kann man folgenderweise zusammenfassen. Während der destruktiven Phase oder der Lyse bringt die Elektronenmikroskopie extensive Herde an den Tag, die ohne Zweifel durch Zusammenballung mehrerer Lysis Bereiche hervorgerufen wurden Diese Herde zeichnen sich durch ihre scharf abstechenden Ränder aus, sowie durch die in ihrer unmittelbaren Nähe sehr häufige Anwesen-heit von Mikroherden deren Grösse einige Mikronen nicht überschreitet, und die — wie es scheint — der „Ausbreitungsfront dieser Krankheit vorangehen

Weiter entsteht noch während der Gewebs zerstörung ein sehr charakteristisches Bild durch Zerfaserung und Verlust der charakteristischen Streifung der sehr zahlreichen kollagenen Fa-sern im Knochen. Die Verfasser beschreiben dieses Bild unter der Bezeichnung „Pasteur Pipette Das Aussehen der Zellen wird be sprochen Die Verfasser heben besonders die Tatsache hervor nach der verschiedenen Osteo-cyten degenerative Erscheinungen aufweisen ohne von otospongiosen Prozessen befallen zu sein diese Erscheinungen gehören zum norma-len metabolischen Bild der Labyrinthkapsel.

Ausserdem findet man inmitten der Lyse-Herde Zellen, denen man einen histiozytären Wert zuschreibt Diese Zellen scheinen im Pro-cessus der Lyse eine bedeutendere Rolle zu spielen als die Osteoklasten die klassich für den Zerstörungsprozess verantwortlich gemacht werden. Ein wesentliches Kennzeichen dieser Zellen ist ihr Reichtum an Lysosomen Der physiologische Wert dieser von einer einzigen Membran begrenzten Bläschen, deren Inhalt elektronenundurchlässig ist, ist jetzt bekannt Man schreibt ihnen vor allem die Rolle der Speicherung der hauptsächlichsten hydrolyti schen Enzyme zu, sowie die der Verdauung der fremden Körperchen und der Phagozytenmole küle Aus diesen Angaben geht hervor dass das Zerreissen ihrer Membran die Zerstörung der perizellulären Gewebe hervorrufen kann, sowie eventuell auch das Absterben der Zelle Die selben zytologischen Verhältnisse wurden im Bereich der Causse Osteoidplättchen festge-stellt, die wie Herde otospongioser Knochen in intramuköser Lage in Erscheinung treten

Die enzymatische Theorie die von den Ver

'assern vorgeschlagen wird und die die Lysosome als hauptsächlichstes Element der destruktiven Phase der Otospongiose betrachtet, wurde durch die Untersuchung der sauren Phosphatase-Aktivität im Bereich des otospongiosen Herdes bestätigt. Man schreibt tatsächlich im allgemeinen diesem Ferment einen „Indexwert" der verschiedenen hydrolytischen Aktivitäten zu, die normalerweise in den Lysosomen vorhanden sind.

Die Verfasser haben mit Hilfe der Elektronenmikroskopie eine saure Phosphatase Aktivität nachgewiesen und die genaue Lokalisierung dieser im otospongiosen Knochen angegeben.

1 im Bereich der sich in Zerstörung befindenden Osteozyten oder Histiozyten (besonders im Bereich der intrazytoplasmatischen Lyse-Bezirke, als Folge einer Ruptur der Lysosomenbläschen),

2. im Bereich der Zellenlagunen und der von diesen ausgehenden Kanälchen,

3 im Bezirk der „Ausbreitungsfront" der aktiven otospongiosen Herde (der schmale Streifen mit Enzymaktivität greift immer auf das normale Gewebe über)

4 inmitten der Mikroherde, die der „Ausdehnungsfront" vorausgehen.

Schlussfolgerung

Um die am wenigsten bekannte Phase der Lysis im Otospongiose Herd klarzustellen, legen die Verfasser eine enzymatische Theorie vor die sich auf die hydrolytische Aktivität des Lysosomeninhalts beruft. Diese Theorie erklärt die morphologischen Befunde vollkommen, die durch Untersuchungen am Elektronenmikroskop gewonnen wurden und die für diese Lyse characteristisch sind.

12 Acknowledgements

The authors acknowledge their indebtedness to Professor Marcel Bessis, Director of the Institut de Pathologie Cellulaire, Hôpital du Kremlin-Bicêtre, Paris, for kind hospitality in his Laboratory and to Professor H. K. Kristensen, Director of the University E.N.T. Clinic, Rigshospitalet, Copenhagen, for his constant interest and support during the studies

Henrik Johansen M.D Head of the E.N.T Department, Rigshospitalet, Tagensvej, Copenhagen, and Otto Metz, M.D Head of the E.N.T Department, Bispebjerg Hospital, Copenhagen, have kindly assisted by processing histological material.

We are grateful also to Mr Maurice Lesourd for his valuable technical assistance and to Mrs Ulla Eberth for photomicrography

The studies have been aided by grants from the Rask-Ørsted Fond and Statens Videnskabsfond, Copenhagen.

CONTENTS

Introduction

Individual differences in motion sickness susceptibility have been scored by a pass-fail dichotomy designed primarily for screening highly susceptible individuals and have been ranked according to the level of response to some type of sustained stimulus. However no known method has yielded a single numerical score that would permit comparison of individuals on a continuous scale of susceptibility values. Such a procedure has two major requirements (1) standardization and quantitative definition of symptoms that are reliably diagnostic of a specific level of motion sickness, (2) choice of a stimulus that is effective for the majority of normal subjects and which, for practical purposes, can be generated by simple or conventional apparatus and be readily measured.

The endpoint favored by most investigators of motion sickness susceptibility is the demonstration of frank sickness, viz. severe nausea or vomiting. Such a criterion has certain disadvantages, however in that physiological as well as psychological complications can affect serial measurements (e.g., drug or habituation studies). A more acceptable and definitive approach considers diagnostic criteria based upon symptomatology manifested prior to this severe expression of motion sickness. A guideline for such an approach has recently been proposed (Graybiel et al., 1968) which, in quantitative terms, categorizes specific symptoms and identifies five levels of severity of motion sickness Each of the four endpoints short of frank sickness allows the experimenter to stress his subjects to a nearly equivalent extent without the manifestation of severe symptoms This choice in the test design of an equivalent response criterion, instead of a common schedule of physical forces for all subjects, was made to gain greater differentiation of individual differences, as well as to spare highly susceptible individuals from undue stressor effects and to eliminate the possibility of regarding more resistant ones as immune to motion sickness.

Of the various available means of experimentally provoking symptoms of motion sickness, standardized head (body) movements during constant speed rotation in a rotational chair represent a convenient and highly effective method (Dowd, 1965 Harris et al., 1963 Kraus 1960 Lansberg, 1954 Khilov 1969 Spiegel et al., 1944). The present study evaluated a variation of this general method, but one which was designed specifically to measure individual susceptibility along a common scale of stress with an equal endpoint. The dependent variable was a quantitatively defined malaise level and the independent variable the physical dimension of a standardized Coriolis stimulus

Procedure

Subject

The normal group consisted of 250 men, of whom 193 were aviation students or flight crew personnel the remaining 57 were comprised of 11 nonaviator officers, 41 enlisted men, and 5 civilians with flying assignments. Their ages ranged from 16 to 43 years all but 18 were between 19 and 26 years of age.

In addition to the standard medical examina

Introduction

Individual differences in motion sickness susceptibility have been scored by a pass-fail dichotomy designed primarily for screening highly susceptible individuals and have been ranked according to the level of response to some type of sustained stimulus. However no known method has yielded a single numerical score that would permit comparison of individuals on a continuous scale of susceptibility values. Such a procedure has two major requirements. (1) standardization and quantitative definition of symptoms that are reliably diagnostic of a specific level of motion sickness (2) choice of a stimulus that is effective for the majority of normal subjects and which, for practical purposes, can be generated by simple or conventional apparatus and be readily measured.

The endpoint favored by most investigators of motion sickness susceptibility is the demonstration of frank sickness, viz., severe nausea or vomiting. Such a criterion has certain disadvantages, however in that physiological as well as psychological complications can affect serial measurements (e.g., drug or habituation studies) A more acceptable and definitive approach considers diagnostic criteria based upon symptomatology manifested prior to this severe expression of motion sickness A guideline for such an approach has recently been proposed (Graybiel et al 1968) which, in quantitative terms, categorizes specific symptoms and identifies five levels of severity of motion sickness. Each of the four endpoints short of frank sickness allows the experimenter to stress his subjects to a nearly equivalent extent without the manifestation of severe symptoms. This choice in the test design of an equivalent response criterion, instead of a common schedule of physical forces for all subjects, was made to gain greater differentiation of individual differences, as well as to spare highly susceptible individuals from undue stressor effects and to eliminate the possibility of regarding more resistant ones as immune to motion sickness.

Of the various available means of experimentally provoking symptoms of motion sickness, standardized head (body) movements during constant speed rotation in a rotational chair represent a convenient and highly effective method (Dowd, 1965 Harris et al., 1963 Kraus, 1960 Lansberg, 1954 Khilov 1969 Spiegel et al. 1944). The present study evaluated a variation of this general method, but one which was designed specifically to measure individual susceptibility along a common scale of stress with an equal endpoint. The dependent variable was a quantitatively defined malaise level and the independent variable, the physical dimension of a standardized Coriolis stimulus.

Procedure

Subjects

The normal group consisted of 250 men, of whom 193 were aviation students or flight crew personnel the remaining 57 were comprised of 11 nonaviator officers, 41 enlisted men, and 5 civilians with flying assignments. Their ages ranged from 16 to 43 years, all but 18 were between 19 and 26 years of age

In addition to the standard medical examina-

he was secured by a lap belt in the Stille rotary chair and a blindfold was put over his eyes to eliminate any visual influences.

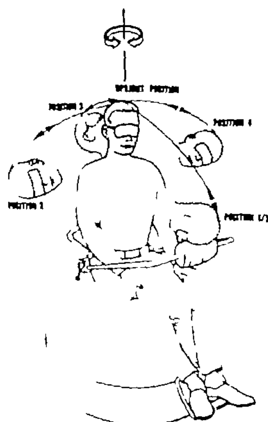

Fig. 1. Diagram of standardized procedure for making each sequence of head movements to and from tilt position 1 through 5 during chair rotation.

While stationary the subject was required to demonstrate the standardized head movement sequence which would provide the Coriolis accelerations during chair rotation: front, upright, pause; right, upright, pause; back, upright, pause; left, upright, pause; front, upright, rest (Fig. 1). Each 90° tilt movement or the return to upright was executed smoothly over a 1-sec period. The pauses between movements were of the same (1 sec) duration, with the final pause (rest) lasting for 20 sec. A taped recording was used to standardize the temporal sequence of head movements.

With the subject in an upright position, the chair was accelerated 5°/sec² either in the clockwise or counterclockwise direction, selected at random, until one of several constant velocities was reached (2.5, 5.0, 7.5, 10.0, 12.5, 15.0, 20.0, 25.0, 30.0 rpm). Sixty seconds later the test was begun with the first head movement sequence. The sequences were continued until the cumulative point score of the symptoms totaled at least 8, the lowest number of points in the M III criterion (Graybiel et al., 1968). Immediately upon manifesting M III the subject terminated his head movements and returned to his upright position, the chair was decelerated at 5°/sec² to a stop. Specific motion sickness signs and symptoms were scored on a tally sheet (Appendix C) as they appeared. With this aid, even an observer with only a minimal amount of training could record the

[b] III = severe or marked, II = moderate, I = slight.

tion required by the Navy Department, all subjects were given specific tests of otolith (ocular counterrolling) (Miller II 1961 1966) and semicircular canal function (caloric threshold) (McLeod & Meek, 1962) and oculogyral illusion threshold (Graybiel & Hupp 1946) Each of the normal subjects manifested vestibular responses which were well within normal limits

Three completely deaf persons with total or severe bilateral loss of semicircular canal and otolith function (Miller II & Graybiel 1963) acted as control subjects

Method

The procedure for measuring motion sickness susceptibility to Coriolis forces included a pretest evaluation of the subject for individual selection of stimulus level (chair velocity) and general fitness a simple method of scoring diagnostic criteria of motion sickness (Table I) and the grading of an individual in terms of a quantitative measure (index) of Coriolis sickness susceptibility derived from the cumulative head movements executed at a given chair velocity

The predetermined endpoint for each subject was severe malaise (M III) The desired level of motion stress imposed upon each subject was such that this level of malaise was approached rather gradually so that the observer could readily identify and register symptoms in sequence as they were manifested, but more importantly so that the subject was not overstimulated, particularly to the point of extreme nausea or vomiting (frank sickness) For these reasons, the Motion Experience Questionnaire (MEQ) (Appendix A) based on the Pensacola Motion Sickness Questionnaire (Hardacre & Kennedy 1963) was used in conjunction with Table II as the basis for selecting the rotational rate for testing each subject.

Table II lists the best estimate of the chair's rotational test rate (rpm) which we were able to gain empirically from the average level of experience (X) and intensity of symptoms (S) reported in the MEQ Usefulness of Table II is demonstrated by the fact that, by this table an rpm could be predicted which yielded M III in approximately 80% of the 250 subjects at between 40 and 166 head movements.

The subject's fitness for testing was established from his completed Preexperimentation Questionnaire (Appendix B) After both questionnaires were evaluated the subject was briefed on the symptoms he could expect. Then

With the subject in an upright position, the chair was accelerated 5 /sec² either in the clockwise or counterclockwise direction, selected at random, until one of several constant velocities was reached (2.5 5.0 7.5 10.0 12.5 15.0, 20.0, 25.0 30.0 rpm) Sixty seconds later the test was begun with the first head movement sequence. The sequences were continued until the cumulative point score of the symptoms totaled at least 8 the lowest number of points in the M III criterion (Graybiel et al., 1968) Immediately upon manifesting M III, the subject terminated his head movements and returned to his upright position, the chair was decelerated at 5 /sec² to a stop Specific motion sickness signs and symptoms were scored on a tally sheet (Appendix C) as they appeared. With this aid, even an observer with only a minimal amount of training could record the

symptomatology efficiently and stop the test precisely when the endpoint was reached.

The Coriolis sickness susceptibility index

The stress effect of a standard head tilt as a function of chair velocity was measured in another study (Miller II & Graybiel 1970) by determining among several subjects the number of head tilts required to elicit a common malaise level at each of several different chair velocities Individually the regularity of this function was limited to rotational rates above a critical amount, that which apparently stressed the subject beyond his functional vestibular reserve (FVR) (Graybiel, 1969) When the rpm was reduced below this point there was characteristically a sudden marked increase in the subject s capacity for making head movements without evoking symptoms.

When head movements at a given chair velocity introduce vestibular stress in excess of the FVR, the average relative stimulus effect of a single head movement[1] can be expressed by the factor E which is linearly related (log/log function) to chair velocity (Fig 2) (Miller II & Graybiel 1970) Each individual's score, referred to as his *Coriolis Sickness Susceptibility* Index or CSSI therefore can be calculated simply by multiplying the appropriate E factor for the rpm used in his test by the number of head movements (N) required to elicit M III

$$\mathrm{CSSI} = E \times N$$

The resultant value expresses quantitatively motion sickness susceptibility to Coriolis acceleration within a single convenient scale of numbers (0 to 100)

It was found in the program of this test s development that when M III occurred within the range of 40 to 166 head movements the signs and symptoms developed regularly and gradually without the hazard of provoking frank sickness If M III was not reached within this range the test was considered invalid and the subject was retested after at least 48 hours had elapsed Any subject tested at 30 rpm who failed to reach the endpoint was not retested since his performance was considered to indicate essential immunity to Coriolis sickness In the retest the chair was rotated in the opposite direction from that of the first test and at a different rpm that was based on the subject s response in the initial test The duration of each test was usually less than 15 min

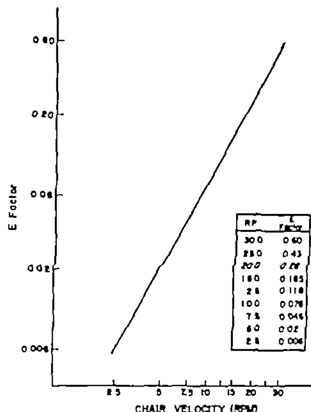

Fig 2 Relationship between average relative stress effect (E factor) of a single head movement and rotational velocity

Test retest evaluation

Thirty unselected subjects whose susceptibility level (CSSI score) had been properly measured were retested at the same rotational rate to determine test retest reliability The standard Spearman (rank) method revealed the degree of relationship between the rankings of the individual CSSI scores calculated for the two test sessions

[1] Head movement in the four directions as required in this test is not equally stressful (Guedry & Montague, 1961 Ichiro et al., 1963) and the effect of direction of movement varies among individuals and occasionally even in the same individual

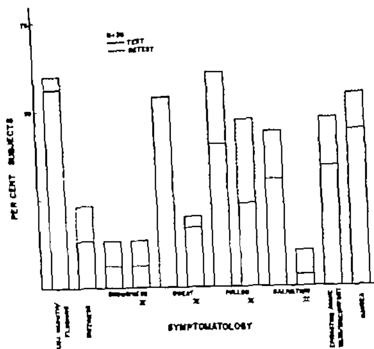

Fig. 6. Similarity of symptomatology patterning between the test and retest of Coriolis susceptibility of 30 normal subjects.

Discussion

The index of Coriolis sickness susceptibility is valid only within certain limits of the number of head movements which, in turn, are dependent upon the chair's rotational rate. Six subjects (A, B, C, D, E, F, Fig. 7) were selected from the 250 normal ones to serve as examples of the difference in the rate of the buildup of symptoms and to illustrate the need for careful selection of chair velocity. An ideal type of response in terms of rate of symptom buildup falls near to or within the limits represented by subjects D and E. As a rule, it was extremely difficult, if not impossible, at times to prevent a skyrocketing of symptoms up to the level of frank sickness (FS), as illustrated by subjects A and B who manifested the typical response obtained when the rpm is too high for the individual. If, on the other hand, the rpm selected for him is too low, he can continue to make head movements without provoking any symptoms (subject F). There were other subjects who at first displayed mild symptoms, but these decreased and disappeared as the test progressed; however, when each of these subjects was retested at an rpm which yielded a stressor condition above that for which he could compensate, a pattern of response similar to that of subjects D and E was seen. The rest period between head movement sequences was found to be short enough so that any appreciable recovery from previous vestibular Coriolis stimulation did not occur, yet it allowed for the characteristic lag in the appearance of motion sickness symptoms after each exposure to a head movement sequence.

The distribution of Coriolis sickness susceptibility index (CSSI) values among the population of 250 unselected normal subjects of this study revealed that most normal individuals are moderately or highly susceptible to Coriolis stress; therefore, the suggested binomial distribution function (Brand & Perry 1966) is inappropriate. The fact that our population of subjects was formed predominantly of flight

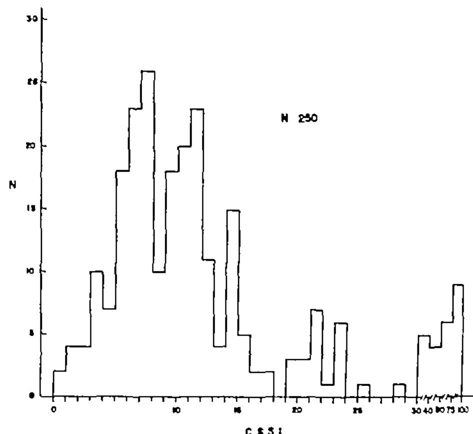

Fig 4 Distribution of Coriolis Sickness Susceptibility Index (CSSI) among 250 normal subjects.

bility to Coriolis motion sickness in this population, although the maximum rotational rate did not provoke symptoms in three of the 250 subjects

Test Retest Reliability The Coriolis Sickness Susceptibility Index of 30 subjects as determined with the M III criterion in test and retest sessions correlated highly ($\rho = 0.89$) A scattergram plot (Fig. 5) reveals that none of the subjects changed substantially in his level of susceptibility from one session to the next.

The patterning of symptoms for the group was remarkably similar (Fig. 6) in these two test sessions, and, individually almost identical symptoms in terms of number type and intensity were provoked in the majority of cases

LABYRINTHINE DEFECTIVE (L D) SUBJECTS

None of the L D subjects experienced even the slightest symptom or unpleasant feeling during or following the execution of up to 300 head movements at the highest rotational velocity of the chair (30 rpm)

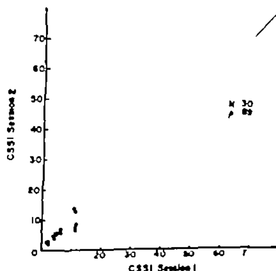

Fig 5 Scattergram of test vs. retest Coriolis Sickness Susceptibility Indices (CSSI) of 30 normal subjects.

Discussion

The index of Coriolis sickness susceptibility is valid only within certain limits of the number of head movements which, in turn, are dependent upon the chair's rotational rate. Six subjects (A, B, C D E, F Fig. 7) were selected from the 250 normal ones to serve as examples of the difference in the rate of the buildup of symptoms and to illustrate the need for careful selection of chair velocity An ideal type of response in terms of rate of symptom buildup falls near to or within the limits represented by subjects D and E As a rule it was extremely difficult, if not impossible at times to prevent a skyrocketing of symptoms up to the level of frank sickness (FS), as illustrated by subjects A and B who manifested the typical response obtained when the rpm is too high for the individual if on the other hand, the rpm selected for him is too low he can continue to make head movements without provoking any symptoms (subject F). There were other subjects who at first displayed mild symptoms, but these decreased and disappeared as the test progressed however when each of these subjects was retested at an rpm which yielded a stressor condition above that for which he could compensate, a pattern of response similar to that of subjects D and E was seen. The rest period between head movement sequences was found to be short enough so that any appreciable recovery from previous vestibular Coriolis stimulation did not occur yet it allowed for the characteristic lag in the appearance of motion sickness symptoms after each exposure to a head movement sequence.

The distribution of Coriolis sickness susceptibility index (CSSI) values among the population of 250 unselected normal subjects of this study revealed that most normal individuals are moderately or highly susceptible to Coriolis stress, therefore the suggested binomial distribution function (Brand & Perry 1966) is inappropriate. The fact that our population of subjects was formed predominantly of flight

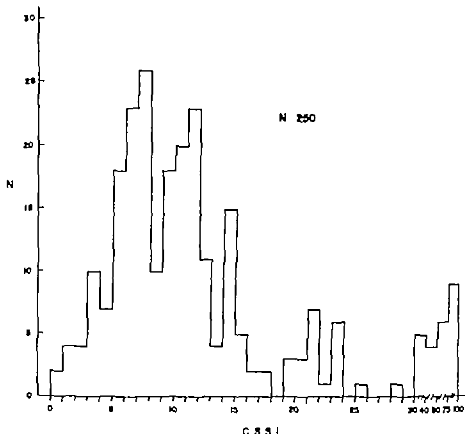

Fig 4 Distribution of Coriolis Sickness Susceptibility Index (CSSI) among 250 normal subjects.

bility to Coriolis motion sickness in this population, although the maximum rotational rate did not provoke symptoms in three of the 250 subjects

Test Retest Reliability The Coriolis Sickness Susceptibility Index of 30 subjects as determined with the M III criterion in test and retest sessions correlated highly ($\rho = 0.89$) A scattergram plot (Fig. 5) reveals that none of the subjects changed substantially in his level of susceptibility from one session to the next.

The patterning of symptoms for the group was remarkably similar (Fig 6) in these two test sessions and individually almost identical symptoms in terms of number type and intensity were provoked in the majority of cases

LABYRINTHINE DEFECTIVE (L D) SUBJECTS

None of the L D subjects experienced even the slightest symptom or unpleasant feeling during or following the execution of up to 300 head movements at the highest rotational velocity of the chair (30 rpm)

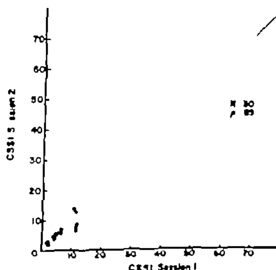

Fig 5 Scattergram of test vs. retest Coriolis Sickness Susceptibility Indices (CSSI) of 30 normal subjects.

ferent directions for a limited number of times, covering the eyes, and if the test was repeated, reversing the direction of rotation (CW CCW) were procedures introduced to increase the complexity of the stimulus, and to decrease experiential factors, thereby reducing the subject's ability to habituate to the test conditions. Furthermore, a chair velocity was carefully selected which would stress the individual at a level greater than his capability for making compensatory adjustments, i.e., above his functional vestibular reserve. These procedures probably contributed to the high test-retest reliability in this and in a preceding study (Miller II et al. 1969).

The stability of the results which are expressed quantitatively within a single scale of values, renders this test highly useful in specifying individual susceptibility as well as in determining the influence of a variety of factors (e.g., drugs, training) upon this basic measurement. Simplicity of the test, the short time period required, and use of apparatus commonly found in a vestibular laboratory are practical advantages.

Zusammenfassung

Eine Standardmethode für Quantifizierung der Empfänglichkeit für Coriolis (See) Krankheit wurde mit 250 normalen und drei Labyrinthdefekten Versuchspersonen ausgewertet. Die Versuchsperson musste eine bestimmte Kopfbewegung (±90° in der Front und Seitenebene) ausführen, während sie in einem Stuhl sass, der mit jeweils einer von verschiedenen konstanten Geschwindigkeiten rotierte. Die geeignete Versuchsgeschwindigkeit wurde vorhergesagt in der Mehrzahl der Fälle mit Hilfe des Motion Experience Fragebogens. Drei normale und alle Labyrinth-defekten Personen erwiesen sich als unempfänglich bei diesen Versuchsbedingungen. Der Seekrankheitsempfänglichkeit Index CSSI wurde für jede Versuchsperson bestimmt durch Multiplizierung des gefundenen E Faktors, d. h. des mittleren Stressfaktors für jede Kopfbewegung bei der Umdrehungszahl des Versuches, mit der Zahl der erforderlichen Kopfbewegungen, um starke Malaise zu erzeugen (M III). Die gefundenen CSSI *Werte für* die 250 Versuchspersonen lagen im Bereich von 0.4 bis 100, doch war die Verteilung deutlich nach rechts verschoben. Das Verfahren ergab eine hohe Reproduzierbarkeit ($\rho = 0{,}89$) der CSSI Werte und im Symptomenablauf. Wenn der Malaise III Grad erreicht wurde, zeigte sich in den meisten Fällen das Übelkeitssyndrom, doch blieb ein signifikanter Prozentsatz (9,6%) der Versuchspersonen frei von epigastrischer Störung oder Übelkeit.

personnel would seem to indicate that substantial adverse response to Coriolis acceleration would be the rule rather than the exception in the general population

The essentiality of the vestibular organs in the genesis of motion sickness was again demonstrated by the fact that the subjects lacking the function of these organs remained symptomless when exposed to the severest Coriolis acceleration provided by this test. On the other hand, the fact that three of the subjects with confirmed normal vestibular function were similarly resistant to the same stressful conditions reveals that the corollary is not always true and demonstrates the marked individual differences in susceptibility which occur among normal subjects

With the aid of one minor qualification, the diagnostic criteria for categorizing different levels of severity of acute motion sickness as reported previously (Graybiel et al., 1968) served without exception in quantitatively grading the susceptibility of all subjects The need to alter the original schema was revealed when a large percentage (72 4%) of the 250 subject group (Fig 3) reported an acute increase in apparent body warmth of ≥ II intensity which was occasionally but not usually accompanied by flushing, the objective counterpart of elevated skin temperature For this reason a moderate or greater increase in the subject's feeling of warmth ("subjective warmth") was regarded in this test as equivalent to flushing and, singly or in combination with flushing was identified as an Additional Qualifying Symptom (AQS) with a value of a single point.

Either nausea I epigastric discomfort, or epigastric awareness was the predominant feature of severe malaise (III) However a proportion of the test population (9 6%) failed to manifest even the mildest form of gastrointestinal disturbance This finding is not in agreement with the classical viewpoint which for the most part equates motion sickness with a gastrointestinal reaction marked by nausea or vomiting. If M III as diagnosed by a nonnausea symptom complex is equivalent in terms of the subject's well being his psychomotor efficiency or some other indicator to that involving the nausea syndrome then the restricted "nausea syndrome" criterion of motion sickness must be reevaluated

Attention was given in the design of this test to factors which would reduce or if possible eliminate habituation Moving the head in dif

ferent directions for a limited number of times, covering the eyes, and if the test was repeated, reversing the direction of rotation (CW CCW) were procedures introduced to increase the complexity of the stimulus, and to decrease experiential factors, thereby reducing the subject's ability to habituate to the test conditions. Furthermore a chair velocity was carefully selected which would stress the individual at a level greater than his capability for making compensatory adjustments i.e., above his functional vestibular reserve. These procedures probably contributed to the high test-retest reliability in this and in a preceding study (Miller II et al., 1969)

The stability of the results, which are expressed quantitatively within a single scale of values, renders this test highly useful in specifying individual susceptibility as well as in determining the influence of a variety of factors (e.g. drugs, training) upon this basic measurement. Simplicity of the test, the short time period required, and use of apparatus commonly found in a vestibular laboratory are practical advantages.

Zusammenfassung

Eine Standardmethode für Quantifizierung der Empfänglichkeit für Coriolis (See) Krankheit wurde mit 250 normalen und drei Labyrinth defekten Versuchspersonen ausgewertet. Die Versuchsperson musste eine bestimmte Kopf bewegung (± 90 in der Front und Seitenebene) ausführen, während sie in einem Stuhl sass, der mit jeweils einer von verschiedenen konstanten Geschwindigkeiten rotierte. Die geeignete Versuchsgeschwindigkeit wurde vorhergesagt in der Mehrzahl der Fälle mit Hilfe des Motion Experience Fragebogens. Drei normale und alle Labyrinth-defekten Personen erwiesen sich als unempfänglich bei diesen Versuchsbedingungen. Der Seekrankheitsempfänglichkeit Index CSSI wurde für jede Versuchsperson bestimmt durch Multiplizierung des gefundenen E Faktors, d. h. des mittleren Stressfaktors für jede Kopfbewegung bei der *Umdrehungszahl* des Versuches, mit der Zahl der erforderlichen Kopfbewegungen um starke Malaise zu erzeugen (M III). Die gefundenen CSSI *Werte* für die 250 Versuchspersonen lagen im Bereich von 0,4 bis 100 doch war die Verteilung deutlich nach *rechts* verschoben. Das Verfahren ergab eine hohe Reproduzierbarkeit (r = 0,89) der CSSI Werte und im Symptomenablauf Wenn der *Malaise III Grad* erreicht wurde zeigte sich in den meisten Fällen das Übelkeitssyndrom doch blieb ein signifikanter Prozentsatz (9,6 %) der Versuchspersonen frei von epigastrischer Störung oder Übelkeit.

Appendix A

MOTION EXPERIENCE QUESTIONNAIRE INSTRUCTION FOR THE EXAMINER

In attempting to evaluate motion sickness susceptibility based upon this (historical) account by the subject, two primary factors are used. (1) type and number of exposures to motion and (2) the effects in terms of the average intensity of symptoms which were recalled in these experiences. These factors, the subject's experience (X) and intensity of symptoms (S) for each of the motion environment categories, are identified in the Questionnaire by X and S and coded on a five-point scale. If symptoms are indicated for the "Swings and other Gymnastic Equipment" category (page 19) its X and S values are used in the calculations, otherwise this category is omitted entirely. The fact that this category is infrequently used increases its significance when filled in, and the X and S values are arbitrarily weighted by a factor of 2×. The average of the 9 (or 10) X and 10 (or 11) S values are used in conjunction with a table that lists the appropriate empirically derived estimate of the chair velocity to be used in testing each subject.

MOTION EXPERIENCE QUESTIONNAIRE

PART I

Name ______________ Date, Mo ____ Da ____ Y ____ Age Yrs __ M __

Serial No. ________ Rank or Rate ____________ Designator ____________

Circle: Male or Female Date of birth ________ Weight ________ Height ________ Handedness R L

Code *0* *1* *2* *3* *4* *5* Code Answer ______

Trigger with right (Code *R*) or left (Code *L*) hand? Code Answer ______

Average number of pistol rounds fired per year ______

Average number of rifle rounds fired per year ______

8 Exposure to high intensity noise?
If YES (*Code 1*), describe. Code Answer ______

9 Have you ever had an ear illness or any injury or illness which was accompanied by dizziness and/or nausea? Code Answer ______

Approximate Date(s) ______

10. In the past 8 weeks have you been nauseated FOR ANY REASON?
If YES (Code *1*), explain. Code Answer ______

a. In the past you

Code

0 — Were never nauseated in youth or adult life
1 — Could never vomit when nauseated
2 — Would retch and finally vomit
3 — Vomited easily Code Answer ______

11 Have you ever had a serious head injury? Code Answer ______
If YES

a When? ______

b. Describe ______

12 Almost all pilots have had one or more experiences with vertigo and/or disorientation.
How many have you had?

None Less than five Five to ten More than ten

Code *0* *1* *2* *3* Code Answer ______

13 Most people experience faintness or dizziness two or three times a year which is not the result of motion.
During the past year have you experienced faintness or dizziness?

Never Less than this The same as this More than this

Code *0* *1* *2* *3* Code Answer ______

14 Have you been exposed to any rotational test within the past 48 hours
If yes, describe. Code Answer ______

PART III

Motion sickness susceptibility is revealed by a wide variety of subjective symptoms and objective signs resulting from various types of motion and may be experienced over a wide range of severity Common symptoms are discomfort lack of appetite, nausea dizziness and drowsiness, common signs are pallor sweating, increased salivation and vomiting. Most persons recall accurately severe symptoms but not mild symptoms which, even when experienced, may not have been attributed to motion In identifying your motion sickness susceptibility you should relate the acute onset of symptoms to the onset of motion. Symptoms of fear and anxiety do not qualify as indicators of susceptibility to actual motion.

Indicate by the proper code taken from the appropriate table below and for each type of motion listed, I, the *number of exposures* and II, the *intensity of the symptoms* experienced during your youth and adult life.

I *Exposure* Code:
None Leave Blank
1–10 *1*
10–25 *2*
25–50 *3*
50–100 *4*
100 *5*

II. *Intensity of symptoms*
Code: None Leave Blank; Very mild *1*; *2*; *3*; *4*; Very severe *5*

	I Exposure	General Discomfort	Nausea (Code 1–4)	Vomited or Retched (Code 5)	Stomach awareness or discomfort	Increased salivation	Giddiness, dizziness or vertigo	Drowsiness	Cold sweating	Increased body warmth (not from exercise)	Headache	Pallor

Appendix B

SUBJECT'S PREEXPERIMENTATION QUESTIONNAIRE

Name/Number ____________________ Date __________ Time __________

Have you been well throughout the past week?
YES NO

Are you free of all major health complications? (e.g. heart disease, diabetes, back trouble, etc.)
YES NO

Are you in your usual state of fitness today?
YES NO

If no to one or more of the above questions, specify problem and include severity, time course, where localized, etc.

How much alcohol have you consumed during the past 24 hours? (No. and kinds of drinks)

How much tobacco in past 3 hours
Cigarette( ) Cigar(s) Pipe(s) ful

Have you taken drugs or medicines of any kind in the past 24 hours?
YES NO

If yes, what type? If name of drug( ) is known, please list below
- Analgesic (aspirin) __________
- Sedative or tranquilizer __________
- Anti-motion sickness remedy (Anti-histamine) __________
- Other including ear and eye drop medications __________

How many hours sleep did you get last night? Was this sufficient?
YES NO

How anxious are you regarding your participation in these tests?
NOT MINIMAL MODERATE GREAT VERY GREAT

How many hours since your last meal?

How many cups of fluid have you had in the past 2 hours?

Have you served as a subject in any rotational test within the past 48 hours? If yes, endpoint reached.
YES NO

5a. Have you ever taken part in any activities which involved unusual body rotation (dance, game, etc.)? YES (Code 1) NO (Code 0)

Code Answer ________

b. What were they? ____

c. How severe was the motion?

Very mild				Very severe
1	*2*	*3*	*4*	*5*

Code Answer \ ________

d. What was the average intensity of these symptoms?

Very mild				Very severe
1	*2*	*3*	*4*	*5*

Code Answer \ ________

e. What were your specific symptoms?

____

6. How prone are you to car sickness?

	Not at all	Minimally	Slight	Moderately	Very	Extremely
Code	*0*	*1*	2	*3*	*4*	*5*

Code Answer S ________

7 It is thought that there are two kinds of motion sickness. One starts in the brain (dizziness, sleepiness) and the other one starts in the stomach or intestines (vomiting, nausea) Which would you say was typically most like yours?

	Brain	Stomach
Code	*B*	*S*

Code Answer ________

8a. Identify by code the general level of motion sickness susceptibility of your blood relatives when exposed to substantial motion (at sea, in flight or carnival devices, etc.).

Code.		Blood relative	
Leave Blank —	Unknown	Father	Code Answer ________
0 —	Never gets sick	Grandfather	Code Answer ________
1 —	Rarely gets sick	Grandmother	Code Answer ________
2 —	Sometimes	Mother	Code Answer ________
3 —	Frequently	Grandfather	Code Answer ________
4 —	Most of the Time	Grandmother	Code Answer ________
5 —	Always	Other	Code Answer ________

CONTENTS

I Introduction

The pathogenesis of the symptom complex which constitutes Ménière's disease or idiopathic endolymphatic hydrops has remained enigmatic. Recent experimental and clinical observations indicate however that an anatomically and physiologically intact endolymphatic sac and endolymphatic duct are requisite for long term maintenance of normal inner ear fluid physiology.

Endolymphatic hypertension or increased pressure within the labyrinth was theoretically suggested (1) as an underlying cause for the clinical triad described earlier by Ménière (3). However little experimental work relating the role of the endolyphatic sac to increased endolymphatic pressure was attempted until Portmann studied the anatomy and the pathophysiology of the endolymphatic sac in lower animals (4 5 6). From these studies Portmann advanced the concept that endolymphatic hypertension in man was the causative factor in Ménière's disease. This concept was clinically applied (7) when the endolymphatic sac was decompressed surgically for clinical endolymphatic hydrops (the Portmann procedure) (8 9 10 11). At about the same time Guild (12) suggested that endolymphatic hydrops would occur with failure of the pars intermedia (rugose portion) to function (resorb endolymph) further that blockage of the endolymphatic duct itself would result in distention of all parts of the membranous labyrinth. Eleven years later the classic histopathologic descriptions of Hallpike & Cairns (13 14) confirmed many of these hypotheses. Interest in the role of the endolymphatic sac in the pathogenesis of clinical endolymphatic hydrops (Ménière's disease), however languished in the ensuing years.

Long term ablative studies on the endolymphatic sac and endolymphatic duct in the guinea pig (15 16 17) cat (17 18 19 20), chinchilla (17) squirrel monkey (17) and rabbit (20), have refocused attention on the definite but species-specific and time-dependent role of the endolymphatic sac and duct in the experimental production of histologically demonstrable endolymphatic hydrops. These results significantly modified the conclusions drawn from the earlier and relatively *short term* ablative studies in monkeys (21) and cats, (22, 23 24), which had failed to show histologically a significant degree of endolymphatic hydrops. Similar relatively short term ablative studies on rabbits (25 26) failed to demonstrate clinical signs consistent with endolymphatic hydrops.

At about the same time that these long-term experimental investigations were in progress, (15 16, 17 18) there was a resurgence of interest in the surgical management of patients with Ménière's disease, and in the Portmann procedure or its modifications (27–33). In addition, other conservation of hearing procedures which involved drainage or release of an increased volume of endolymph from the endolymphatic sac (34–45) and other forms of decompression surgery were being done (46–54). No surgical procedure constructive or destructive however found widespread acceptance (55–58).

During this renaissance of experimental and surgical interest in the endolymphatic sac, Shambaugh observed (38, 59) at surgery a decreased vascularity ("ischemia") of the endolymphatic sac wall in many idiopathic endolymphatic hydrops patients when compared to patients who had the endolymphatic sac un-

I Introduction

The pathogenesis of the symptom complex which constitutes Ménière's disease or idiopathic endolymphatic hydrops has remained enigmatic. Recent experimental and clinical observations indicate, however, that an anatomically and physiologically intact endolymphatic sac and endolymphatic duct are requisite for long term maintenance of normal inner ear fluid physiology.

Endolymphatic hypertension or increased pressure within the labyrinth was theoretically suggested (1, 2) as an underlying cause for the clinical triad described earlier by Ménière (3). However, little experimental work relating the role of the endolyphatic sac to increased endolymphatic pressure was attempted until Portmann studied the anatomy and the pathophysiology of the endolymphatic sac in lower animals (4, 5, 6). From these studies Portmann advanced the concept that endolymphatic hypertension in man was the causative factor in Ménière's disease. This concept was clinically applied (7) when the endolymphatic sac was decompressed surgically for clinical endolymphatic hydrops (the Portmann procedure) (8, 9, 10, 11). At about the same time, Guild (12) suggested that endolymphatic hydrops would occur with failure of the pars intermedia (rugose portion) to function (resorb endolymph), further that blockage of the endolymphatic duct itself would result in distention of all parts of the membranous labyrinth. Eleven years later the classic histopathologic descriptions of Hallpike & Cairns (13, 14) confirmed many of these hypotheses. Interest in the role of the endolymphatic sac in the pathogenesis of clinical endolymphatic hydrops (Ménière's disease), however, languished in the ensuing years.

Long term ablative studies on the endolymphatic sac and endolymphatic duct in the guinea pig (15, 16, 17), cat (17, 18, 19, 20), chinchilla (17), squirrel monkey (17), and rabbit (20), have refocused attention on the definite, but species-specific and time-dependent role of the endolymphatic sac and duct in the experimental production of histologically demonstrable endolymphatic hydrops. These results significantly modified the conclusions drawn from the earlier and relatively *short term* ablative studies in monkeys (21) and cats, (22, 23, 24) which had failed to show histologically a significant degree of endolymphatic hydrops. Similar relatively short term ablative studies on rabbits (25, 26) failed to demonstrate clinical signs consistent with endolymphatic hydrops.

At about the same time that these long-term experimental investigations were in progress, (15, 16, 17, 18) there was a resurgence of interest in the surgical management of patients with *Ménière's* disease, and in the Portmann procedure or its modifications (27–33). In addition, other conservation of hearing procedures which involved drainage or release of an increased volume of endolymph from the endolymphatic sac (34–45) and other forms of decompression surgery were being done (46–54). No surgical procedure, constructive or destructive, however, found widespread acceptance (55–58).

During this renaissance of experimental and surgical interest in the endolymphatic sac, Shambaugh observed (38, 59) at surgery a decreased vascularity ("ischemia") of the endolymphatic sac wall in many idiopathic endolymphatic hydrops patients when compared to patients who had the endolymphatic sac un-

covered during translabyrinthine removal of an acoustic neurilemmoma. The surgical observations by Shambaugh & Clemis (37 38, 59 60 61) of endolymphatic sac wall ischemia, fibrosis and intraluminal adhesions in patients with Ménière's disease have been further substantiated histopathologically (38 60 62, 63 64)

Shambaugh & Clemis currently favor bony decompression of the endolymphatic sac alone (without opening the sac) as the procedure of choice in patients with an early case of clinical idiopathic endolymphatic hydrops with vertigo intractable to medical management, and in which there is hearing worth preserving. Because of this relative contraindication to opening the endolymphatic sac at surgery additional biopsies of the sac wall by these authors are not likely to be taken in the foreseeable future Even with the statistically significant (see statistical study which follows) but highly selective and small series of six biopsy specimens of clinical idiopathic endolymphatic hydrops, these previously reported histopathologic biopsy reports (60 62 63 64) must still be considered preliminary and in need of confirmation

II Histologic Studies

The aim of this report is to strengthen further the histopathologic observations, already reported (60 62, 63 64) of the distinctly abnormal state of the endolymphatic sac epithelium and subepithelial connective tissue in patients with Ménière's disease by comparing our previous biopsy specimens with a larger "normal" or control series of human endolymphatic sacs dissected after necropsy For the most part, the specimens were sectioned undecalcified (and decalcified only when necessary due to the presence of calculi, dystrophic calcification or subepithelial bone) A more satisfactory examination of the histology is possible with undecalcified, dissected specimens. This approach precludes the artifacts produced by prolonged processing and decalcification especially regarding the status of the lining epithelia, the perisaccular connective tissue, and its vascular and lymphatic supply

The detailed case reports of those patients who underwent biopsy of the lateral wall of the endolymphatic sac at the time of endolymphatic sac decompression and drainage surgery were reported elsewhere (60 62) along with the details of the processing and the most pertinent histologic findings. Fig. 1 shows the epithelial distortion in a biopsy specimen from a patient with Ménière's disease It is presented from a previous publication (62) for comparison of the biopsy material with our series of normals Table I (Appendix) summarizes the pertinent clinical history of those patients biopsied, and correlates this information with surgical, histopathologic and polytomographic observations and postoperative results. The clinical implications and surgical indications in these cases (60 67) will be suggested only when all of the information and observations are correlated. Statistics are used to compare the biopsy and necropsy material to determine the significance of the observations made

MATERIALS AND METHODS

As a source of controls and to emphasize the significant abnormalities noted in the biopsy specimens (60 62) endolymphatic sacs were dissected at necropsy from patients with no recorded history of hearing loss (except one patient with presbycusis) This series consisted of 28 sacs from 16 patients, ranging from neonates to an 86-year-old patient (see Appendix, Table II, for age–sex distribution) The dissected material included the endolymphatic sac from the posterior portion of the petrous bone, the proximal interosseous portion (rugose) and the distal intradural portion with a portion of sigmoid sinus and surrounding dura. The specimens were obtained by the use of a dental drill, middle ear instruments, and a Zeiss operating microscope. They were fixed in 10% neutral buffered formalin, dehydrated in graded series of alcohols, but unlike the biopsies were then embedded in paraffin so that thinner serial sections at 8–10 micra could be obtained. It was hoped that this technique would minimize the distortion of the cellular elements and soft tissues encountered in routine temporal bone histopathologic studies caused by decalcification (65), and the additional difficulties inherent in evaluating thick celloidin sections either from bioptic material or temporal bone studies. The following special stains, in addition to Ehrlich's hematoxylin and eosin, were used to help elucidate histochemical characteristics of the endolymphatic sac: Alcian

blue and PAS (mucopolysaccharide) Masson s trichrome (connective tissue), Van Gieson s (elastic and reticulin fibers) and von Kossa (calcium)

RESULTS

Biopsy specimens

The following is a summary of the findings of the biopsy specimens correlated with the clin ical history observations at surgery and pre operative hypocycloidal polytomography The original biopsy patients could be readily di vided into three groups (see Appendix, Table I) Group I ($n = 2$) consisted of those *patients* with clinical idiopathic endolymphatic hydrops *in which the endolymphatic duct* was de monstrated by hypocycloidal polytomography *on the affected side* despite the histologic changes (Fig 1) in the sac (64) and who clin- ically had had the disease for less than two years Remnants of the endolymphatic sac were histologically present but abnormal This group had a favorable result from sac surgery (relief of vertigo and preservation of hearing)

The second group ($n = 4$) consisted of those patients with idiopathic endolymphatic hydrops in which the endolymphatic duct and/or the endolymphatic sac were not demonstrated by hypocycloidal polytomography on the affected side but were visualized on the contralateral side This group had the disease clinically for more than two years Small remnants of endolymphatic sac epithelium were found in- frequently however when present, they were markedly abnormal and distorted With the ex ception of one patient (Case No 4) this group did not benefit from decompression surgery

The third group ($n = 2$) consisted of one patient with symptoms of endolymphatic hydrops secondary to perilymph fistula (Case No 7) (66 67) and another patient with simi lar complaints secondary to congenital lues (Case No 8) (67–73) In both of these cases a *normal* endolymphatic sac and endolymphatic duct were demonstrated radiographically by polytomography The endolymphatic sac epi thelium of both patients appeared essentially normal Neither patient benefited from surgery a finding which was in agreement with previous observations by one of the authors (G E S, Jr) (37 38 42)

Normal microscopic anatomy of the *endolymphatic sac*

The normal microscopic and descriptive ana- tomy of the endolymphatic sac in man has been *reported* (74–96) *and reviewed in detail* (83 92) These studies in man have been prepared *by routine celloidin embedding and thick sec* tioning except for the studies by Sirala (81) *and Secretan* (82) *in which the special thin* celloidin paraffin sectioning method of von *Fiendt & Saxen* (97 98) was used In all these previously reported studies of normal sac with the exceptions noted some soft tissue (espe cially epithelial distortions) were observed

A most recent histologic report on the hu man endolymphatic duct and sac by Zechner & Altmann (96) described many normal mor phologic variations and revealed some new morphologic detail but in regard to Ménière s disease the epithelial changes were con- sidered less important than the obvious fibro- sis of the perisaccular connective tissue They stated that they were unable to find a peri saccular fibrosis in 190 temporal bones from individuals without Ménière s disease com parable to that found in their cases (temporal bones) with Ménière s disease The epithelial cells were described as varying from normal cuboidal to columnar or even pseudostratified. Occasionally protoplasmic processes of epi thelial cells were noted in the subepithelial connective tissue Epithelial hyperplasia was also noted The noncellular intraluminal con tents of hyalinized masses of bony calculi were mentioned

A description of the various portions of the human endolymphatic duct and endolymphatic sac and a nomenclature was proposed by Bast & Anson (83) *They described a sinus and*

isthmus portion of the endolymphatic (otic) duct and three parts of the endolymphatic (otic) sac: the proximal or rugose portion, the sac proper or enlarged flattened portion, and the distal projection. This terminology rather than the more common terminology of the endolymphatic sac established by Guild (99) for experimental animals (100–105) (pars proximalis, pars intermedius, and pars distalis) will be utilized in this report.

In our series ($n = 28$) of normal endolymphatic sacs removed at necropsy the following observations were made. The epithelium was mainly cuboidal (Fig. 2) but varied from a low cuboidal or simple squamous-like epithelium in the proximal portion and distal projection of the endolymphatic sac (Fig. 3 and 4) to a high cuboidal or columnar type of epithelium in the rugose portion (Fig. 5). There was, however a frequent variation in height of epithelial cells, not attributed to plane of sectioning (Fig. 6 and 7). These variations suggest the possibility of a transitional type of epithelium as is found in the urinary bladder able to expand with changes of intrasaccular pressure and thus consistent with the pressure regulating role attributed mainly to the intradural portion of the endolymphatic sac. Epithelial protoplasmic processes into the subjacent connective tissue were infrequently noted (Fig. 8) as previously described (81 82, 96).

True villi (Fig. 9 and 10) were distinguished from simple rugae or folds (Fig. 11) by the presence of a vascular-lymphatic pedicle within the subepithelial connective tissue of the villus. This distinction is important because of the loss of a vascular-lymphatic pedicle in all biopsy specimens from patients with Ménière's disease. By all anatomic criteria these villi could be involved in fluid transport. The hypothesis that the loss of villi in Ménière's disease may be of etiologic importance should be thoroughly examined. These folds also may play a role in the pressure regulating function along with the transitional-like epithelium. Zechner (96) also described a pseudostratified columnar type of epithelium found in response to inflammation. We did not find classical pseudo tratified epithelium but demonstrated occasional areas of stratified and irregularly oriented epithelium. This type of epithelium was apparently a focal metaplasia, most likely an inflammatory or irritative response to intraluminal concretions and/or detritus. These focal areas of metaplasia appeared to consist of layers of surface cuboidal epithelium with a concomitant change in the orientation of their nuclear axis from perpendicular to horizontal in relation to the basement membrane (Fig. 4 and 13). Desquamated or exfoliated epithelial cells were noted in large aggregates within the endolymphatic sac lumen (Fig. 14). In addition, there were specimens in which epithelial hyperplasia was evident and often multifocal (Fig. 15). Other areas of epithelial proliferation (Fig. 16) appeared similar to the fimbriated bodies of pigeon endolymphatic sac described by Ormerod (106). It is also possible that these represent adenomata of the sac epithelium.

Supranuclear and infranuclear epithelial clear spaces (which may be argued to be artifact) (Fig. 17) appeared frequently but irregularly and were consistent with secretory or transportation vacuoles (Fig. 18). The absence of a continuous PAS positive basement membrane in our materials and others (96 107 108) directly related to the presence of vacuoles or "vesicles" was suggestive of significant pinocytotic movement of fluid according to Gussen (107 108). In addition, the luminal surface of the epithelial cells often showed cytoplasmic globules projecting into the lumen of the sac (Fig. 18). This is often associated with "breaks" in the basement membrane (incomplete PAS positive basement membrane) at the light microscopic level. This suggests significant fluid transport by pinocytosis (107–108) rather than herpetic viral vesiculations as suggested by Lempert et al. (109) and House (110) for other portions of the membranous labyrinth. Unfortunately these findings also are consistent with autolysis and a definitive statement may not yet be made. Normal appearing

blue and PAS (mucopolysaccharide) Masson s trichrome (connective tissue) Van Gieson s (elastic and reticulin fibers) and von Kossa (calcium)

RESULTS

Biopsy specimens

The following is a summary of the findings of the biopsy specimens correlated with the clinical history observations at surgery and pre operative hypocycloidal polytomography The original biopsy patients could be readily divided into three groups (see Appendix Table I) Group I ($n = 2$) consisted of those patients with clinical idiopathic endolymphatic hydrops in which the endolymphatic duct was demonstrated by hypocycloidal polytomography on the affected side, despite the histologic changes (Fig. 1) in the sac (64) and who clinically had had the disease for less than two years. Remnants of the endolymphatic sac were histologically present, but abnormal This group had a favorable result from sac surgery (relief of vertigo and preservation of hearing)

The second group ($n = 4$) consisted of those patients with idiopathic endolymphatic hydrops in which the endolymphatic duct and/or the endolymphatic sac were not demonstrated by hypocycloidal polytomography on the affected side but were visualized on the contralateral side This group had the disease clinically for more than two years Small remnants of endolymphatic sac epithelium were found infrequently however when present, they were markedly abnormal and distorted With the exception of one patient (Case No 4) this group did not benefit from decompression surgery

The third group (n 2) consisted of one patient with symptoms of endolymphatic hydrops secondary to perilymph fistula (Case No 7) (66 67) and another patient with similar complaints secondary to congenital lues (Case No 8) (67–73) In both of these cases a *normal* endolymphatic sac and endolymphatic duct were demonstrated radiographically by polytomography The endolymphatic sac epithelium of both patients appeared essentially normal Neither patient benefited from surgery a finding which was in agreement with previous observations by one of the authors (G E. S., Jr) (37 38 42)

Normal microscopic anatomy of the endolymphatic sac

The normal microscopic and descriptive anatomy of the endolymphatic sac in man has been reported (74–96) and reviewed in detail (83 92) These studies in man have been prepared by routine celloidin embedding and thick sectioning except for the studies by Siirala (81) and Secretan (82) in which the special thin celloidin paraffin sectioning method of von Flendt & Saxen (97 98) was used In all these previously reported studies of normal sac, with the exceptions noted some soft tissue (especially epithelial distortions) were observed

A most recent histologic report on the human endolymphatic duct and sac by Zechner & Altmann (96) described many normal morphologic variations and revealed some new morphologic detail but in regard to Ménière s disease the epithelial changes were considered less important than the obvious fibrosis of the perisaccular connective tissue They stated that they were unable to find a perisaccular fibrosis in 190 temporal bones from individuals without Ménière s disease comparable to that found in their cases (temporal bones) with Ménière s disease The epithelial cells were described as varying from normal cuboidal to columnar or even pseudostratified Occasionally protoplasmic processes of epithelial cells were noted in the subepithelial connective tissue Epithelial hyperplasia was also noted The noncellular intraluminal contents of hyalinized masses of bony calculi were mentioned

A description of the various portions of the human endolymphatic duct and endolymphatic sac and a nomenclature was proposed by Bast & Anson (83) They described a sinus and

Figures 1–4

1. The endolymphatic sac epithelium from patient with Ménière disease (case 1) shows disorganization and nuclear pyknosis. Many epithelial cells are flattened. Note the giant cell (arrow) and the distinctly dense subepithelial connective tissue. A lumen is macroscopically patent (H & E, 400).

2. Normal cuboidal epithelium. Note an occasional fibroblast-like cell below the basement membrane (H & E, 130).

3. In the distal portion of the endolymphatic sac, epithelial height decreases. Within the lumen is a typical assortment of giant cells and detritus (H & E, 315).

4. Squamous (possibly metaplastic) epithelium often occurs in areas where coarse intraluminal detritus is present (H & E, 1260).

epithelial cells interestingly were present in elderly patients when the distal sac wall was collapsed and the epithelial surfaces were in apposition (Fig. 19) This was true even as far as the distal area of the sigmoid sinus (Fig. 20) This observation seemed quite significant when compared to loss of epithelial integrity in the bioptic material (Fig. 1) No evidence of the distortion and loss of epithelium seen in the six biopsies of Ménière s disease was observed in the necropsy specimens Often, large epithelial cells appeared to be either breaking away from the surface to become free-floating phagocytes secreting mucoprotein or engulfing globules of endolymph (Fig 11 and 21) Occasionally cysts (Fig 22) were found arising from the epithelial surface containing highly protein aceous endolymph (19) or early eosinophilic hyaloid masses (Fig. 23 and 24) This re presents protein and mucopolysaccharides in traluminally There was a distinct continuum of eosinophilic or PAS positive endolymph apparently due to concentration effects, from early hyaloid eosinophilic masses (Fig 23 and 24) to dense eosinophilic masses of endolymph within the complicated canalicular system or apparently isolated side pouches (Fig. 25 and 26) as described by Watzke & Bast (84) This process may involve a continuous gradient and include concretions (Fig 26) calculi (Fig 27) and intraluminal bone (Fig. 28) A related process may account for the subepithelial localiza tion of concretions (Fig 29) and dystrophic calcification (Fig. 30) or even bone (Fig. 31)

There was a significant, but highly variable accumulation within the lumen of the endolymphatic sac of free cells of various types (Fig 3 6 12 14 31 32 33 34) giant cells (Fig. 32, 34) detritus (Fig 35 36 37 38) detached cysts surrounded by epithelium (Fig 39) and cellular aggregates (Fig. 14) Clumps of nucleated cells and red blood cells were also found in the endolymphatic sac of a newborn, consistent with that described by Zechner & Altmann (96) in newborns with tentorial ruptures (Fig. 40)

Statistical study

The range of normal variation in the microscopic anatomy of the endolymphatic sac in man has been demonstrated by the examina tion of our material of dissected endolymphatic sacs which were not subjected to decalcifica tion These data were used to emphasize statistically the markedly abnormal status of the endolymphatic sac wall biopsies taken during the endolymphatic sac decompression and drainage procedures (60 62 63 64) Absence, agenesis, or possibly atrophy of old age (9) of the endolymphatic sac in approximately (maximum) 10% of the temporal bones studied (34) or observed at surgery by House (34) Shambaugh (38, 42, 60 62) and Caw thorne (44) appeared to be a significant observation This can occur without clinical symptoms of endolymphatic hydrops. On the contrary Bast & Anson (84) and Richany et al (93) feel that the endolymphatic sac can al ways be demonstrated histologically

In our statistical study (specimens of endolymphatic sac, $n=28$) using the exact proba bility test for a 2×2 contingency table the observed difference (association between histopathologically abnormal endolymphatic sac biopsy specimens and idiopathic endolymphatic hydrops) in proportions of abnormal endolymphatic sac between the select small biopsy group and the random postmortem group is significant at the 1% level ($p<0.001$) In ad dition, assuming a maximum of 10% occur rence of abnormal sacs in the general popula tion (without idiopathic endolymphatic hy drops) there would be one chance in one mil lion that in a sample of 6 all would be abnormal ($p\leq0.001$) Therefore, although the biopsy sample was small, the pathology appeared to be statistically significant.

Figures 1–4.

1. The endolymphatic sac epithelium from patient with Ménière's disease (case 1) shows disorganization and nuclear pyknosis. Many epithelial cells are flattened. Note the giant cell (arrow) and the distinctly dense subepithelial connective tissue. A lumen is microscopically patent (H & E, ×500).

2. Normal cuboidal epithelium. Note an occasional fibroblast-like cell below the basement membrane (H & E, ×150).

3. In the distal portion of the endolymphatic sac, epithelial height decreases. Within the lumen is a typical assortment of giant cells and detritus (H & E, ×315).

4. Squamous (possibly metaplastic) epithelium often occurs in areas where coarse intraluminal detritus is present (H & E, ×160).

epithelial cells, interestingly were present in elderly patients when the distal sac wall was collapsed and the epithelial surfaces were in apposition (Fig 19) This was true even as far as the distal area of the sigmoid sinus (Fig. 20) This observation seemed quite significant when compared to loss of epithelial integrity in the bioptic material (Fig. 1) No evidence of the distortion and loss of epithelium seen in the six biopsies of Ménière s disease was observed in the necropsy specimens Often large epithelial cells appeared to be either breaking away from the surface to become free-floating phagocytes, secreting mucoprotein or engulfing globules of endolymph (Fig 11 and 21) Occasionally cysts (Fig. 22) were found arising from the epithelial surface containing highly proteinaceous endolymph (19) or early eosinophilic hyaloid masses (Fig 23 and 24) This represents protein and mucopolysaccharides intraluminally There was a distinct continuum of eosinophilic or PAS positive endolymph apparently due to concentration effects, from early hyaloid eosinophilic masses (Fig. 23 and 24) to dense eosinophilic masses of endolymph within the complicated canalicular system or apparently isolated side pouches (Fig. 25 and 26) as described by Watzke & Bast (84) This process may involve a continuous gradient and include concretions (Fig. 26), calculi (Fig. 27) and intraluminal bone (Fig 28) A related process may account for the subepithelial localization of concretions (Fig. 29) and dystrophic calcification (Fig. 30) or even bone (Fig. 31)

There was a significant, but highly variable accumulation within the lumen of the endolymphatic sac of free cells of various types (Fig 3 6 12, 14 31 32 33 34) giant cells (Fig. 32, 34) detritus (Fig 35 36 37 38) detached cysts surrounded by epithelium (Fig. 39) and cellular aggregates (Fig. 14) Clumps of nucleated cells and red blood cells were also found in the endolymphatic sac of a newborn, consistent with that described by Zechner & Altmann (96) in newborns with tentorial ruptures (Fig 40)

Statistical study

The range of normal variation in the microscopic anatomy of the endolymphatic sac in man has been demonstrated by the examination of our material of dissected endolymphatic sacs which were not subjected to decalcification These data were used to emphasize statistically the markedly abnormal status of the endolymphatic sac wall biopsies taken during the endolymphatic sac decompression and drainage procedures (60 62 63 64) Absence agenesis, or possibly atrophy of old age (9) of the endolymphatic sac in approximately (maximum) 10 of the temporal bones studied (34) or observed at surgery by House (34) Shambaugh (38 42 60 6?) and Cawthorne (44) appeared to be a significant observation This can occur without clinical symptoms of endolymphatic hydrops. On the contrary Bast & Anson (84) and Richany et al (93) feel that the endolymphatic sac can always be demonstrated histologically

In our statistical study (specimens of endolymphatic sac, $n = 28$) using the exact probability test for a 2×2 contingency table the observed difference (association between histopathologically abnormal endolymphatic sac biopsy specimens and idiopathic endolymphatic hydrops) in proportions of abnormal endolymphatic sac between the select small biopsy group and the random postmortem group is significant at the 1 level ($p < 0.001$) In addition, assuming a maximum of 10 occurrence of abnormal sacs in the general population (without idiopathic endolymphatic hydrops) there would be one chance in one million that in a sample of 6 all would be abnormal ($p \leq 0.001$) Therefore although the biopsy sample was small the pathology appeared to be statistically significant.

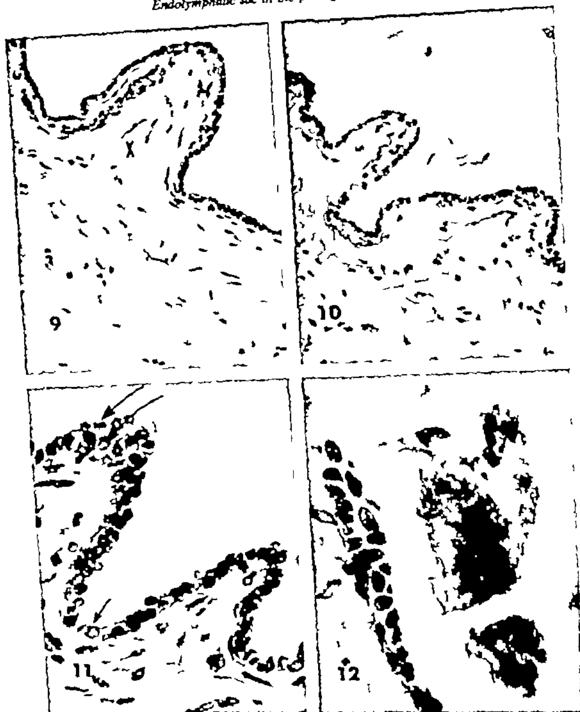

Figure 9–12

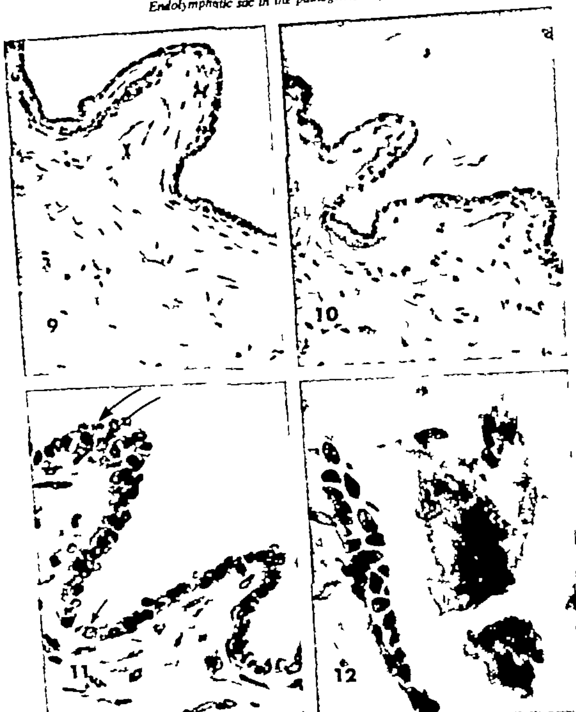
9. [illegible] occur in the rugose portion of the endolymphatic sac of neonates. These [illegible] vascular lymphatic pedicle [illegible] than the loose subepithelial connective tissue. Note separate lymphatic-like channel ( ) (H & E, × 280).

10. A ruga or fold does not contain [illegible] vascular-lymphatic complex as found in villi. It is possible that these rugae play an important role in the pressure regulating function of the endolymphatic sac as well as in absorption (H & E, × 280).

11. These large living cells (arrows) morphologically suggest either resorption of endolymph or secretion of mucopolysaccharides (H & E, × 650).

12. Two layers of epithelial cells with vesicular nuclei are noted near condensations in the endolymph. There are desquamated surface cells within the lumen (H & E, × 1170).



F gu es 5–8

5 Low columnar epithelium frequently demonstrates surface "blebs (arrows) (H & E, 1150).

6 Occasionally the epithelium appears pseudostrat fied or tratified. This, however is consistent morphologically with transitional epithelium (see text). Note the occasional cell with a large acuole (arrow) and surface changes consistent with pinocyto l movement of fluid (arrow) A degenerating cell lies within the lumen (H & E, 1150).

7 Often the epithelium appears multilayered This occurs when there is a surface change in response to irritation by large aggregates of detritus and cal culi. These surface cha ges tend to distort epithelial integrity (H & E, 1150)

8. Subepithelial cytoplasmic extensions occur (ar row) (H E 1150

Figs. 9–12.

9. These [illegible] occur in the rugose portion of the endolymphatic sac of neonates. These have [illegible] vascular lymphatic pedicle [illegible] than the loose subepithelial connective tissue. Note separate lymphatic-like channel (H & E, [illegible]).

10. A ruga or fold does not contain [illegible] vascular lymphatic complex as found in [illegible]. It is possible that these rugae play an important role in the pressure regulating function of the endolymphatic sac as well as in absorption (H & E, 280).

11. These large living cells (arrows) morphologically suggest either resorption of endolymph or secretion of mucopolysaccharides (H & E, 650).

12. T[illegible] layers of epithelial cells with vesicular nuclei are noted near condensations in the endolymph. There are desquamated surface cells within the lumen (H & E, 1120).

Figure 13 16

13 Below the squamous l ke epithelium are mac rophages and possibly a plasma cell in the perisaccular connective tissue (H & E, 1 60)

14 A large aggregate of desquamated epithelium is present within the lumen (PAS, 315)

15 Epithelial hyperplasia occurs and is often multifocal. These hyperplastic cells ha e a prickl cell appearance This epithelial hyperpla ia wa followed through many serial sect ons (H & F 500)

16. Proximally the sac lumen is patent (arrow) Distally the endolymphatic sac epithelium ends a-ruptly in a tortuous infolded ma s. This may be either an adenoma or a structure nal gous to the fimbriated body reported in the endolymphatic sac of pigeons. (H & F 1 5)

Figs. 17–20.

17. Epithelium with large clear spaces (subepithelial) at one [illegible] occur near epithelium with surface blebs or vesicles (luminal arrow). This is suggestive of either diverse cell types or two different functional states of the same cell (see text) (H & E, ×1150).

18. Similarly two types of epithelial cells can again be seen (arrows) with flattening or extrusion [illegible] epithelial cells (F) into the lumen. This is also suggestive of fluid transport (H & E, ×1150).

19. The distal projection of the endolymphatic sac is lined by low cuboidal epithelium which often lies in apposition without loss of luminal or epithelial integrity (H & E, ×115).

20. Often the distal projection of the endolymphatic sac or tip (arrow) extends to the dural (sigmoid) sinus (SS) with patent uncluttered lumen (L) (H & E, ×45).

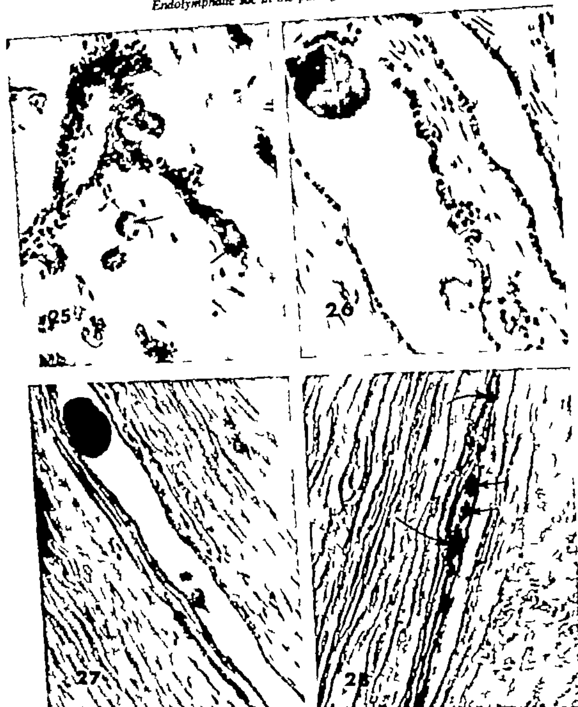


Figure 21 24

1 A large intra-epithelial vacuole of proteinaceous (eosinophilic) material is demonstrated (arrow) (H & E, 1150).

29 Subepithelial concretion surrounded by a slight inflammatory response. It appears to be "breaking through the epithelial surface (H & E 280).

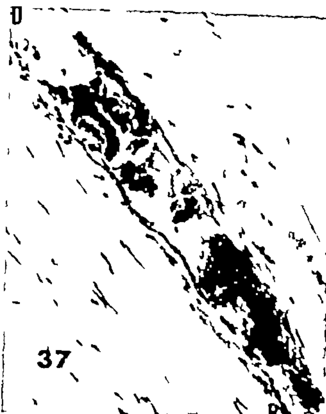
30. Subepithelial dystrophic calcification or bone is seen associated with *normal cuboidal epithelium* without evidence of inflammation. Note the peri succula connective tissue is loose nd well as cularized (H & E. 115).

31 Subepithelial bone is present with metaplastic epithelia apparent only on the abnormal surf ce No inflammatory response is evident (H & E 400)

3_ I tral minal granul r endolymph is strongly *PAS positive Some lining cell appear to be under* going degeneration (H & E. 1150).

III Discussion

Research on the function of the endolymphatic sac has been neglected and requires further elucidation. In a literature review (111) (see Appendix) all of the histologically confirmed cases of noninflammatory (112–114) endolymphatic hydrops in patients with clinical symptoms consistent with Ménière's disease were reviewed. This review (tabulated as Table III, Appendix) (13 14 38, 65 114–145) was directed to the histologic description of the endolymphatic sac and the role (if any) attributed to the sac in the production of hydrops.



A variety of functions have been attributed over the years to the endolymphatic sac in man and in experimental animals. secretion of endolymph (101 145 146) mucopolysaccharide metabolism (147 148), protein metabolism (106 151 164), resorption of endolymph (12, 81 82, 83 99 149 150 151 153) resorption of metabolic wastes (15) and proteins (148, 154 155) phagocytosis (151), filtration (150, 152), pressure regulation (82, 83 156–163), pinocytosis (104 155) reservoir (100, 165–168), both secrete and absorb endolymph (104), and, a non-functional atavistic structure (74 75 104 169). Which of these functions or malfunctions thereof would predispose a patient to the *maladie du Ménière* cannot be conclusively answered at this time. A conceptual synthesis of the generally accepted functions for endolymphatic sac and the integration of the concepts of longitudinal and radial flow of endolymph is presently in order. This may direct and focus attention on future experimental studies regarding this structure (111)

BASIC CONSIDERATIONS

An abnormal histologic state exists in the endolymphatic sac of patients with idiopathic endolymphatic hydrops or Ménière's disease as demonstrated in six biopsy specimens. This was corroborated by a review of cases of idiopathic endolymphatic hydrops in which the endolymphatic sac was microscopically described (see Appendix) The most commonly reported autopsy finding in the literature was the presence of perisaccular fibrosis or the absence of the loose subepithelial connective tissue. The loose subepithelial connective tissue transmits a vascular lymphatic pedicle and forms the structural basis for the villi. Abnormal or pathologic states of the epithelium lining the endolymphatic sac had not been described consistently as being pathognomonic in medically intractable endolymphatic hydrops before the contributions by Shambaugh et al. (60, 62, 64) Previous investigators were unwilling to trust their observations of epithelial abnormalities because of autolysis and preparation artifact. Since the biopsy material was fixed immediately after excision and not decalcified, the changes in the epithelium are considered significant and not attributable solely to autolysis or postmortem changes.

The epithelium lining the endolymphatic sac is distinctly abnormal in our biopsy material when compared to the necropsy control series. The loss of epithelial integrity is consistent with an old cytopathic inflammatory response, possibly viral in origin, as originally suggested by Shambaugh (60) Other types of inflammatory and infectious processes which may produce similar changes in the endolymphatic sac or in endolymphatic pressure have been reported (73 155 170, 171 172) A marked perisaccular fibrosis of the biopsy specimens was evident when compared to the necropsy series. There was good correlation between pathologic changes of the endolymphatic sac—perisaccular fibrosis, and loss of epithelial integrity—and Ménière's disease.

III Discussion

Research on the function of the endolymphatic sac has been neglected and requires further elucidation. In a literature review (111) (see Appendix) all of the histologically confirmed cases of noninflammatory (112–114) endolymphatic hydrops in patients with clinical symptoms consistent with Ménière's disease were reviewed. This review (tabulated as Table III Appendix) (13 14 38, 65 114–145) was directed to the histologic description of the endolymphatic sac and the role (if any) attributed to the sac in the production of hydrops.

A variety of functions have been attributed over the years to the endolymphatic sac in man and in experimental animals: secretion of endolymph (101 145 146), mucopolysaccharide metabolism (147 148), protein metabolism (106, 151 164), resorption of endolymph (12, 81 82, 83 99 149 150 151 153), resorption of metabolic wastes (15) and proteins (148, 154 155), phagocytosis (151) filtration (150 152), pressure regulation (82, 83 156–163) pinocytosis (104 155), reservoir (100 165–168), both secrete and absorb endolymph (104), and, a non-functional atavistic structure (74 75 104 169). Which of these functions or malfunctions thereof would predispose a patient to the *maladie du Ménière* cannot be conclusively answered at this time. A conceptual synthesis of the generally accepted functions for endolymphatic sac and the integration of the concepts of longitudinal and radial flow of endolymph is presently in order. This may direct and focus attention on future experimental studies regarding this structure (111).

BASIC CONSIDERATIONS

An abnormal histologic state exists in the endolymphatic sac of patients with idiopathic endolymphatic hydrops or Ménière's disease as demonstrated in six biopsy specimens. This was corroborated by a review of cases of idiopathic endolymphatic hydrops in which the endolymphatic sac was microscopically described (see Appendix). The most commonly reported autopsy finding in the literature was the presence of perisaccular fibrosis or the absence of the loose subepithelial connective tissue. The loose subepithelial connective tissue transmits a vascular lymphatic pedicle and forms the structural basis for the villi. Abnormal or pathologic states of the epithelium lining the endolymphatic sac had not been described consistently as being pathognomonic in medically intractable endolymphatic hydrops before the contributions by Shambaugh et al. (60 62, 64). Previous investigators were unwilling to trust their observations of epithelial abnormalities because of autolysis and preparation artifact. Since the biopsy material was fixed immediately after excision and not decalcified, the changes in the epithelium are considered significant and not attributable solely to autolysis or postmortem changes.

The epithelium lining the endolymphatic sac is distinctly abnormal in our biopsy material when compared to the necropsy control series. The loss of epithelial integrity is consistent with an old cytopathic inflammatory response, possibly viral in origin, as originally suggested by Shambaugh (60). Other types of inflammatory and infectious processes which may produce similar changes in the endolymphatic sac or in endolymphatic pressure have been reported (73 155 170, 171 172). A marked perisaccular fibrosis of the biopsy specimens was evident when compared to the necropsy series. There was good correlation between pathologic changes of the endolymphatic sac—perisaccular fibrosis, and loss of epithelial integrity—and Ménière's disease.

The endolymphatic sac is considered, there

fore, abnormal in patients with Ménière s dis ease and apparently plays a significant ro'e in the pathogenesis of clinical endolymphatic hy drops in man This is particularly true in cases which do not respond to medical therapy and in which symptoms persist for several years. The relatively small group of patients who require surgical intervention for their intractable vertigo may constitute a separate pathologic group from those patients who responded to medical therapy The former group may have an anatomic or histopathologic abnormality of the endolymphatic sac or duct which is per manent and progressive This lesion may over a long period of time produce an irreversible form of endolymphatic hydrops It is possible that patients whose symptoms abate either spontaneously or with medical therapy within a year (173) may fall into other etiologic groups (e g. a vasomotor instability) (174) Such a transitory lesion should not result ini tially in permanent insult to the end organs or the endolymphatic sac In patients diagnosed as having Ménière s disease the percentage demonstrating abnormalities of the endolym phatic sac and/or duct by polytomography was 95% (175 176) This high value indicates however that anatomic abnormalities may be of greater significance than the present study would indicate. Whether these anatomic changes are the primary pathologic focus or the end result of a primary process needs further investigation.

It is speculated that the radial flow of endolymph (132 178–187) which implies localized and rapid formation and resorption of endolymph takes care of the metabolic require ments of the cells lining the scala media, but not those supplied by the Cortilymph (188) Further the longitudinal flow (12 38 81 82 92 99 102 103 149) toward the endolymph atic sac is probably a much slower phenomenon (189) than was originally speculated (12, 99) This may account for the variation in results between the long term and short term ablative studies in various species

The evidence from the biopsy study (60 62) supports the theory that interference with the relatively slow flow of endolymph toward the endolymphatic duct and sac or its resorption places an increased stress on the local re sorptive mechanism which over a long period of time, can result in irreversible clinical and histological endolymphatic hydrops. Local radial circulation maintains local oxygen and metabolic requirements, while longitudinal flow of endolymph aids in bringing detritus to the area where phagocytosis can be most ef fectively carried out and endolymph could be resorbed The vesiculations long noted in the membranous labyrinth are consistent with large movements of fluids (pinocytosis) either locally (radial flow) or to the endolymphatic sac (longitudinal flow) and also autolysis In this theory of phagocytosis, especially the removal of large macromolecules, or the breakdown of large macromolecules into smaller molecules, as suggested by Mygind (190) is inhibited by blockage of lymphatics (evidenced by decrease or absence of loose perisaccular connective tissue which carries the vascular lymphatic complex) then the accumulation of metabolites would attract water resulting in endolymphatic hydrops. Therefore the importance of the endolymphatic sac becomes evident only when its resorptive function is impaired by loss of epithelium in terms of decreased surface area, loss of epithelial integrity decreased blood supply or impaired lymphatic drainage (191)

The endolymphatic sac almost certainly acts as a pressure regulator at least in its distal intradural portion (161) If the patency of the endolymphatic sac lumen is decreased due to inflammation and fibrosis then rapid changes in CSF pressure would remain uncompensated and might result in clinical symptoms

When anatomic abnormalities (perisaccular fibrosis, loss of epithelial integrity or mechanical blockage) metabolic disturbances (electrolyte imbalance and interference with transport mechanisms) or inflammatory processes (viral labyrinthitis) alter the ability of the endolymphatic sac to resorb then the flow of ex

cess endolymph over an extended period of time may lead to clinical and histologic endolymphatic hydrops in man.

CLINICAL CONSIDERATIONS

At decompression surgery (60 61 62) for intractable Ménière's disease, the most consistent findings were *the ischemic appearing sac* wall and the difficulty of locating the lumen of the endolymphatic sac. Clemis & Valvassori (175–176) found by polytomography a markedly narrowed filiform endolymphatic duct (vestibular aqueduct) on the diseased side in a high percentage of patients who had been referred with the clinical diagnosis of Ménière's disease. In contrast, a low percentage was found in patients with other otologic problems. Clemis (175–176) was the first to confirm an obliterated duct at surgery. Obstructions or obliteration of the endolymphatic sac or duct by bone (35 59 96, 117 120, 175 176 192) tumor (116) granulation tissue (116), fibroproliferative arteritis (60, 62, 64) (our case No. 8) and catarrhal swelling of the lining membrane of the (endolymphatic) duct with resultant obstruction of the (intraosseous) endolymphatic duct (70) were other lesions previously reported which may have produced the clinical symptoms of Ménière's disease by means of a mechanical obstruction of the longitudinal flow of endolymph (retention hydrops of Rollin (117)) as speculated by Guild (12).

Clinical observations made at the time of endolymphatic sac drainage and decompression surgery and preoperative polytomographic studies correlated well with our histopathologic observations. All were consistent with a decreased ability of the endolymphatic sac epithelium to resorb endolymph and/or act as a pressure regulator. The following is a preliminary statement of clinical indications and contraindications for endolymphatic sac decompression and drainage surgery based solely on the six biopsy cases in which we were able to make this correlation (see Table I).

Patients with a secondary form of clinical endolymphatic hydrops (Group III) have not generally improved after endolymphatic sac decompression and drainage surgery; therefore in these cases there is no indication for this form of surgery. Patients with primary *idiopathic endolymphatic* hydrops or Ménière's disease, in whom no polytomographic abnormality of the endolymphatic sac and duct was demonstrated and who had had symptoms for only a few years (Group I), generally obtained relief of vertigo and in some cases, preservation of hearing from the surgery. The Group II patients who had polytomographic abnormalities of the endolymphatic sac and duct, generally did not benefit from surgery. The surgical and polytomographic observations on Group II patients correlated well with the histopathologic findings of the biopsy material as follows: (1) the marked fibrosis, (2) decreased distribution of the vascular-lymphatic complex, and (3) absence of any side channels in the more dense lateral aspect of the endolymphatic sac (which was the site of biopsy). This was particularly evident when compared to the residual but abnormal remnants of the side channels of the endolymphatic sac in Group I patients. Clinically Group I patients are considered worthwhile candidates for a simple endolymphatic sac decompression procedure, the earlier the better. In Groups II and III, *this type of surgery has not proved* beneficial and would be contraindicated, based on present knowledge and polytomographic evidence of abnormal endolymphatic sac and duct. In cases of secondary clinical endolymphatic hydrops, this procedure is not indicated. It is recommended, therefore, that early surgical intervention be undertaken only in Group I patients. Polytomography of the endolymphatic sac and duct (175–176) is a necessity in the proper selection of cases for decompression surgery of the endolymphatic sac.

fore abnormal in patients with Ménière s disease and apparently plays a significant role in the pathogenesis of clinical endolymphatic hydrops in man This is particularly true in cases which do not respond to medical therapy and in which symptoms persist for several years The relatively small group of patients who require surgical intervention for their intractable vertigo may constitute a separate pathologic group from those patients who responded to medical therapy The former group may have an anatomic or histopathologic abnormality of the endolymphatic sac or duct which is permanent and progressive This lesion may over a long period of time produce an irreversible form of endolymphatic hydrops. It is possible that patients whose symptoms abate either spontaneously or with medical therapy within a year (173) may fall into other etiologic groups, (e g. a vasomotor instability) (174) Such a transitory lesion should not result initially in permanent insult to the end organs or the endolymphatic sac. In patients diagnosed as having Ménière s disease the percentage demonstrating abnormalities of the endolymphatic sac and/or duct by polytomography was 95% (175 176) This high value indicates, however that anatomic abnormalities may be of greater significance than the present study would indicate Whether these anatomic changes are the primary pathologic focus or the end result of a primary process needs further investigation

It is speculated that the radial flow of endolymph (132, 178–187) which implies localized and rapid formation and resorption of endolymph takes care of the metabolic requirements of the cells lining the scala media, but not those supplied by the Cortilymph (188) Further the longitudinal flow (12 38 81 82 92 99 102, 103 149) toward the endolymphatic sac is probably a much slower phenomenon (189) than was originally speculated (12, 99) This may account for the variation in results between the long term and short term ablative studies in various species.

The evidence from the biopsy study (60 62) supports the theory that interference with the relatively slow flow of endolymph toward the endolymphatic duct and sac or its resorption places an increased stress on the local resorptive mechanism which over a long period of time, can result in irreversible clinical and histological endolymphatic hydrops. Local radial circulation maintains local oxygen and metabolic requirements while longitudinal flow of endolymph aids in bringing detritus to the area where phagocytosis can be most effectively carried out, and endolymph could be resorbed The vesiculations long noted in the membranous labyrinth are consistent with large movements of fluids (pinocytosis) either locally (radial flow) or to the endolymphatic sac (longitudinal flow) and also autolysis. In this theory if phagocytosis especially the removal of large macromolecules or the breakdown of large macromolecules into smaller molecules, as suggested by Mygind (190) is inhibited by blockage of lymphatics (evidenced by decrease or absence of loose perisaccular connective tissue which carries the vascular lymphatic complex) then the accumulation of metabolites would attract water resulting in endolymphatic hydrops. Therefore, the importance of the endolymphatic sac becomes evident only when its resorptive function is impaired by loss of epithelium in terms of decreased surface area, loss of epithelial integrity decreased blood supply or impaired lymphatic drainage (191)

The endolymphatic sac almost certainly acts as a pressure regulator at least in its distal intradural portion (161) If the patency of the endolymphatic sac lumen is decreased due to inflammation and fibrosis, then rapid changes in CSF pressure would remain uncompensated and might result in clinical symptoms.

When anatomic abnormalities (perisaccular fibrosis, loss of epithelial integrity or mechanical blockage) metabolic disturbances (electrolyte imbalance and interference with transport mechanisms) or inflammatory processes (viral labyrinthitis) alter the ability of the endolymphatic sac to resorb then the flow of ex

cess endolymph over an extended period of time may lead to clinical and histologic endolymphatic hydrops in man.

CLINICAL CONSIDERATIONS

At decompression surgery (60 61 62) for intractable Ménière's disease, the most consistent findings were the ischemic appearing sac wall and the difficulty of locating the lumen of the endolymphatic sac. Clemis & Valvassori (175–176) found by polytomography a markedly narrowed filiform endolymphatic duct (vestibular aqueduct) on the diseased side in a high percentage of patients who had been referred with the clinical diagnosis of Ménière's disease. In contrast, a low percentage was found in patients with other otologic problems. Clemis (175–176) was the first to confirm an obliterated duct at surgery. Obstructions or obliteration of the endolymphatic sac or duct by bone (35 59 96 117 120 175 176 192) tumor (116), granulation tissue (116), fibroproliferative arteritis (60, 62, 64) (our case No 8) and catarrhal swelling of the lining membrane of the (endolymphatic) duct with resultant obstruction of the (intraosseous) endolymphatic duct (70) were other lesions previously reported which may have produced the clinical symptoms of Ménière's disease by means of a mechanical obstruction of the longitudinal flow of endolymph (retention hydrops of Rollin (117)) as speculated by Guild (12)

Clinical observations made at the time of endolymphatic sac drainage and decompression surgery and preoperative polytomographic studies correlated well with our histopathologic observations. All were consistent with a decreased ability of the endolymphatic sac epithelium to resorb endolymph and/or act as a pressure regulator. The following is a preliminary statement of clinical indications and contraindications for endolymphatic sac decompression and drainage surgery based solely on the six biopsy cases in which we were able to make this correlation (see Table I)

Patients with a secondary form of clinical endolymphatic hydrops (Group III) have not generally improved after endolymphatic sac decompression and drainage surgery therefore, in these cases there is no indication for this form of surgery. Patients with primary idiopathic endolymphatic hydrops or Ménière's disease, in whom no polytomographic abnormality of the endolymphatic sac and duct was demonstrated and who had had symptoms for only a few years (Group I) generally obtained relief of vertigo and in some cases, preservation of hearing from the surgery. The Group II patients who had polytomographic abnormalities of the endolymphatic sac and duct, generally did not benefit from surgery. The surgical and polytomographic observations on Group II patients correlated well with the histopathologic findings of the biopsy material as follows (1) the marked fibrosis, (2) decreased distribution of the vascular-lymphatic complex, and (3) absence of any side channels in the more dense lateral aspect of the endolymphatic sac (which was the site of biopsy). This was particularly evident when compared to the residual but abnormal remnants of the side channels of the endolymphatic sac in Group I patients. Clinically Group I patients are considered worthwhile candidates for a simple endolymphatic sac decompression procedure the earlier the better. In Groups II and III this type of surgery has not proved beneficial and would be contraindicated, based on present knowledge and polytomographic evidence of abnormal endolymphatic sac and duct. In cases of secondary clinical endolymphatic hydrops, this procedure is not indicated. It is recommended, therefore that early surgical intervention be undertaken only in Group I patients. Polytomography of the endolymphatic sac and duct (175–176) is a necessity in the proper selection of cases for decompression surgery of the endolymphatic sac.

Appendix

Table I

Histopathologic findings in endolymphatic sac biopsies from patients with various types of clinical endolymphatic hydrops correlated with observations at endolymphatic sac decompression and drainage surgery and with preoperative hypocycloidal polytomographic findings

Case no	Age	Diagnosis	Duration of symptoms (vertigo)	Hypocycloidal polytomography	Surgical observations	Histopathology of endolymphatic sac	Results of surgery
Group I							
1 A K.	39	Ménière s disease (idiopathic endolymphatic hydrops) (hypothyroid)	1 y	Shallow notch for endolymphatic sac and endolymphatic duct	Moderate vascularity adhesions of lumen, I. V nicotinic acid at surgery produced typical skin flush, but no changes in sac wall vessels	Moderate fibrosis, collapsed endolymphatic sac with epithelial sur faces in apposition, distorted epithelium noted loss of subepithelial vascular lymphatic complex (Fig. 1)	Relief of vertigo hearing preserved
2 R. M	58	Ménière s disease (idiopathic endolymphatic hydrops)	20 mo	Prominent groove for endolymphatic sac, endolymphatic duct was also noted	Ischemic wall, lumen difficult to find	Only small remnants of endolymphatic sac, mostly epithelial cell layers in apposition, with loss of epithelial integrity absence of loose subepithelial perisaccular connective tissue	Relief of vertigo hearing stable
Group II							
3 L. M	37	Meniere s disease (atypical id opathic endolymphatic hydrops)	3 y	Unable to identify endolymphatic duct, no indentation for endolymphatic sac on affected side, normal groove and duct on unaffected side	Dilated sac wall vessels, lumen found, no endolymph present, parts of endolymphatic sac wall were adherent	Dense connective tissue, flattened and distorted sac epithelium, microscopic lumen present, dense subepithelial connective tissue, and decreased vascular lympha tic complex present	Improved for 1 year then required labyrinthectomy to relieve the recur rent vertigo
4 C. R.	71	Ménière s disease (idiopathic endolymphatic hydrops)	5 y	Unable to see notch for endolymphatic sac or endolymphatic duct, ppeared normal on unaffected side	Normal vascularity no lumen identified, no endolymph present, obliterated sac	Dense f brotic tissue with decreased vascularity abnormal remnant of epithelium, no suggestion of a lumen	Good results 7 dB hearing improvement, no improvement discrimination

5 I B	71	Ménière disease (idiopathic endolymphatic hydrops)	[illegible]	Endolymphatic sac seen normally bilaterally non-visualization endolymphatic duct on affected side, endolymphatic duct seen on unaffected side	Ischemic sac	Dense avascular connective tissue with absence of any remnants of epithelium or lumen	No significant relief of vertigo or other symptoms
6 M E	72	Ménière disease (idiopathic endolymphatic hydrops)	15 y	Asymmetric appearance of endolymphatic sac groove, unable to see endolymphatic duct on affected side	Sac was white and avascular no definite lumen, no endolymph present	Dense fibrotic and avascular piece of tissue, no lumen, no epithelial remnants, no lymphatics	No improvement
Group III							
7 J O	27	Otosclerosis, stapes surgery with perilymph fistula post operatively symptoms resemble endolymphatic hydrops	1 y	Normal endolymphatic sac and endolymphatic duct, focus of otosclerosis right cochlear capsule and severe bilateral cochlear involvement, spotty areas of remineralization after treatment with NaF	Quite vascular sac and lumen identified with some difficulty walls were somewhat adherent, separated filmy adhesions	Lumen present, relatively loose subepithelial connective tissue, part of the endolymphatic sac was seen with normal patency and eosinophilic and basophilic fluid admixed, normal cuboidal epithelium	No improvement
8 P R.	28	Clinical endolymphatic hydrops secondary to congenital syphilis	6 y	Normal endolymphatic sac and endolymphatic duct, normal otic capsule, no osteitic involvement	Large endolymphatic sac, dilated vessels, thick wall, 2 "tapioca" inclusions removed, could not establish communication between endolymphatic sac and endolymphatic duct	Very vascular connective tissue with patent, but small sac partially occluded, by a fibroproliferative type of arteritis	No improvement
Biopsy control							
9 R. R.	41	Acoustic neurilemmoma	3 y but no vertigo, only unsteadiness	Normal endolymphatic sac and endolymphatic duct, right internal auditory canal much larger than the left internal auditory canal	Vascular sac, patent lumen, no difficulty in identification	Patent lumen, no adhesions, normal cuboidal epithelium	Total removal of tumor via translabyrinthine approach

TABLE II

Distribution of normal endolymphatic sac specimens 28 endolymphatic sacs from 16 random necropsies

Group	Spec. no.	Age	Sex	Race	Ear	Hours postmortem

The following review of the status of the endolymphatic sac in histologically confirmed cases of Ménière's disease (endolymphatic hydrops) (see Table III) is given in chronologic order to enable the reader to follow the conceptual development and changes in interpretation of various authors. Hallpike & Cairns (13, 14) first reported on the histopathologic findings in temporal bones, from their observations in two cases of Ménière's disease. In addition to their classic description of the distention of the cochlear duct and saccule (endolymphatic hydrops) they found significant perisaccular fibrosis which they felt might be a predisposing factor in the development of endolymphatic hydrops. This was the first report of endolymphatic hydrops occurring without associated inflammation. Hallpike & Cairns (13, 14) did a "control" study of 13 temporal bones in which two showed what they considered to be abnormal perisaccular tissue. This "control" study weakened their own observations on the abnormality of the perisaccular connective tissue in Ménière's disease since it could apparently occur as a "normal" variation. With a sample of two ($n = 2$) it would have been risky from a statistical point of view to place too much emphasis on these findings. In both of Hallpike & Cairns cases, there was intractable vertigo for which both patients required surgical intervention (Dandy procedure) and from which both patients expired in the early postoperative period.

Yamakawa (115) reported that in a case of Ménière's disease the lumen of the ductus and saccus endolymphaticus, when compared to the opposite side, was narrowed and filled with thick colloidal masses. Nevertheless, he felt that endolymphatic hypertension was a result of oversecretion by the stria vascularis. He studied another set of temporal bone slides prepared by Dr. Wittmaack with similar observations, but neither case was illustrated by photomicrographs.

Hallpike & Wright (116) found in their one endolymphatic hydrops case an unusual degree of collapse of the lumen with close apposition of the lining epithelium of the endolymphatic sac. A red staining colloid material was found in the sac spaces with a conspicuous absence of perisaccular connective tissue. The epithelium was in close contact with the overlying dura.

Rollin (117) reported the findings in five cases of endolymphatic hydrops. Subepithelial (perisaccular) fibrosis was present in two cases (Cases 1 and 2), two cases (Cases 3 and 5) had obstructive lesions of the endolymphatic sac, and in a final case (Case 4), a congenital agenesis of the sac was reported. In Case 1 the affected (left) side had a marked fibrosis of subepithelial connective tissue with collapsed, adherent, and atrophic epithelium. The lumen was narrow and dark colloidal masses were found within it. Remnants of the lumen contained a large amount of subepithelial pigmentation which was greater in the subdural than in the intraosseous portion of the endolymphatic sac. There was, in addition, some bony (lacunar) erosion. The opposite side was described as having a free lumen with clear endolymph and normal folds of epithelium. Rollin felt both his first and second cases showing perisaccular fibrosis were a "retention" type of hydrops, with a loss of function of the resorptive epithelium, due to inflammatory or to degenerative changes. Rollin's second case had chronic agranulocytosis and myeloblastic leukemia and incidental, bilateral otosclerotic foci. On the more affected side (left) there was a smooth epithelium without folds in the interosseous part, while the intradural portion had definite folds with colloidal

The following review of the status of the endolymphatic sac in histologically confirmed cases of Ménière's disease (endolymphatic hydrops) (see Table III) is given in chronologic order to enable the reader to follow the conceptual development and changes in interpretation of various authors. Hallpike & Cairns (13, 14) first reported on the histopathologic findings in temporal bones, from their observations in two cases of Ménière's disease. In addition to their classic description of the distention of the cochlear duct and saccule (endolymphatic hydrops) they found significant perisaccular fibrosis which they felt might be a predisposing factor in the development of endolymphatic hydrops. This was the first report of endolymphatic hydrops occurring without associated inflammation. Hallpike & Cairns (13, 14) did a "control" study of 13 temporal bones in which two showed what they considered to be abnormal perisaccular tissue. This "control" study weakened their own observations on the abnormality of the perisaccular connective tissue in Ménière's disease, since it could apparently occur as a "normal" variation. With a sample of two ($n=2$) it would have been risky from a statistical point of view to place too much emphasis on these findings. In both of Hallpike & Cairns' cases, there was intractable vertigo for which both patients required surgical intervention (Dandy procedure) and from which both patients expired in the early postoperative period.

Yamakawa (115) reported that in a case of Ménière's disease the lumen of the ductus and saccus endolymphaticus, when compared to the opposite side, was narrowed and filled with thick colloidal masses. Nevertheless, he felt that endolymphatic hypertension was a result of oversecretion by the stria vascularis. He studied another set of temporal bone slides prepared by Dr Wittmaack with similar observations, but neither case was illustrated by photomicrographs.

Hallpike & Wright (116) found in their one endolymphatic hydrops case an unusual degree of collapse of the lumen with close apposition of the lining epithelium of the endolymphatic sac. A red staining colloid material was found in the sac spaces with a conspicuous absence of perisaccular connective tissue. The epithelium was in close contact with the overlying dura.

Rollin (117) reported the findings in five cases of endolymphatic hydrops. Subepithelial (perisaccular) fibrosis was present in two cases (Cases 1 and 2), two cases (Cases 3 and 5) had obstructive lesions of the endolymphatic sac, and in a final case (Case 4), a congenital agenesis of the sac was reported. In Case 1 the affected (left) side had a marked fibrosis of subepithelial connective tissue with collapsed, adherent, and atrophic epithelium. The lumen was narrow, and dark colloidal masses were found within it. Remnants of the lumen contained a large amount of subepithelial pigmentation which was greater in the subdural than in the intraosseous portion of the endolymphatic sac. There was, in addition, some bony (lacunar) erosion. The opposite side was described as having a free lumen with clear endolymph and normal folds of epithelium. Rollin felt both his first and second cases showing perisaccular fibrosis were a "retention" type of hydrops, with a loss of function of the resorptive epithelium, due to inflammatory or to degenerative changes. Rollin's second case had chronic agranulocytosis and myeloblastic leukemia and incidental, bilateral otosclerotic foci. On the more affected side (left) there was a smooth epithelium without folds in the interosseous part, while the intradural portion had definite folds with colloidal

material. The epithelium, however remained flattened and almost in apposition without side pouches. There were subepithelial venous congestion and fibrosis. On the right side (normal) there was a wide intraosseous lumen with slightly decreased rugae. There were some epithelial fibrosis and pigment present. He did not feel that these sac changes were related to the hematologic problem since they were essentially unilateral and consistent with a loss of function of the endolymphatic sac

Rollin diagnosed his third case clinically as Ménière s disease and pathophysiologically as a retention hydrops" The patient died of metastatic breast carcinoma and, interestingly metastatic carcinoma was present in the lumen of the endolymphatic sac. The m tastatic carcinoma in the endolymphatic sac interrupted the connection of the endolymphatic sac with its distal part on the left side The lumen was filled with albuminous masses. There was a small area of apparently normal rugose epithelium at the junction of endolymphatic sac with the duct. On the right side (normal hearing) a patent lumen was filled with colloidal fluid The epithelium did not have normal folds and the subepithelial tissue was fibrotic Intradurally the endolymphatic sac was flattened and walls were partly adherent Where actual remnants of lumen were present, they contained lumps of colloidal material In this clinically unilateral case, where both endolymphatic sacs were abnormal but different from each other Rollin felt that the metastatic carcinoma caused the hydrops, either from carcinoma metabolites (toxic) or from mechanical blockage

In the fifth case (117) of unilateral retention hydrops, no clinical history was available to Rollin The patient was described as having a normal endolymphatic sac on the right consistent with his age" On the left side, however there was a focus of osteodystrophic bone, which completely blocked the lumen at the point where the endolymphatic duct widens into the endolymphatic sac. Beyond this point, the endolymphatic sac was collapsed and the epithelium was adherent The saccular part of the endolymphatic duct was enlarged. The retention hydrops in this case was attributed to the *obstruction by a* bony closure.

Rollin s fourth case had bilateral endolymphatic hydrops and similar changes in the endolymphatic sac bilaterally This patient had an abnormally shaped head and congenital idiocy Tuberculosis of the kidney lung and larynx were found at necropsy The endolymphatic duct had a dilated lumen The endolymphatic sac had no distinct lumen and there was a flattened and adherent epithelium There was bony erosion on the medial sides. This was considered a complete obliteration of the endolymphatic sac bilaterally Rollin noted enlarged cochlear aqueducts and questioned the influence of the cerebrospinal fluid on the endolymph and perilymph as a possible predisposing factor in endolymphatic hydrops, but he felt that the abnormal endolymphatic sac was related more certainly to the hydrops of endolymph as this would interfere with resorption.

Lindsay (118) noted changes in the endolymphatic sac but made no initial statement as to their significance rather he emphasized vasomotor instability as the cause for the Ménière s disease He described the lining on the affected side as having fewer folds and convolutions than expected. The lumen was patent, but the surrounding connective tissue appeared fairly dense with fewer dilated capillaries than usual The epithelium appeared in good condition The unaffected side showed no definite abnormality

Altmann & Fowler (119) reported two cases (Cases 1 and 3) of asymmetrical perisaccular fibrosis and one case (Case 2) of bilateral fibrosis. They too considered these findings to be insufficiently significant to be impressive" although in their case of *bilateral fibrosis* they felt that perisaccular fibrosis might be "a predisposing factor in the development of endolymphatic hydrops." The first case had a marked fibrosis on the affected side and a

somewhat less pronounced fibrosis on the healthy side. The intermediate dilation (Sinus II) showed relatively few folds and complete absence of the subepithelial layers of well-vascularized connective tissue. The epithelium was flattened. Many of the recesses contained pink staining colloid-like masses. The endolymphatic sac (Sinus III) was well-filled and considered a normal structure. On the opposite side there was a layer of loose connective tissue· otherwise, the perisaccular tissue was fibrotic. The lumen of the endolymphatic sac was patent bilaterally In the second case, a definite fibrosis was present bilaterally· nevertheless, vasomotor changes were felt to be more important than changes in the resorptive mechanism They described a dilated proximal sinus (endolymphatic duct). In the intermediate part, the perisaccular connective tissue was completely absent, and the number of folds was reduced. The lining epithelium was cuboidal. There were "ramified cells around the lumen with coarse brown granules of hemosiderin pigment. The endolymphatic sac (proprius) was absent from the specimen as the dura was stripped at necropsy Similar changes were described on the opposite side, except there were no pigmented cells, but the perisaccular connective tissue was fibrotic.

Altmann & Fowler's third case (119) had fibrosis only on the less affected side. On the affected side, the endolymphatic duct was reported normal. *The intermediate part* showed a moderate number of folds covered with flattened epithelium. The subepithelial layer of loose areolar tissue was present. The recesses contained small colloid-like concretions. On the less affected side, the endolymphatic duct was normal. The intermediate portion showed a complete absence of the loose subepithelial tissue In reviewing and re-evaluating these cases in 1968 Altmann & Zechner (120) stated that marked fibrosis was noted on the diseased side and somewhat less pronounced fibrosis on the healthy side in a patient with unilateral Ménière s disease (Case 1). In a patient with bilateral involvement, a marked fibrosis was present on both sides (Case 2) In a third patient (Case 3) again with *bilateral* involvement, the number of folds in the pars rugosa was reduced, but the loose subepithelial tissue was present on one side but seemed to be absent on the other side

In 1944 Lindsay (121) reported another clinically diagnosed case of Ménière s disease in which the *aqueductus endolymphaticus* showed fewer convolutions in the second portion than are usually present, but the saccus had been mostly torn away with the dura at autopsy The endolymphatic aqueduct showed less perisaccular connective tissue than was sometimes found. Again he doubted that the hydrops could be explained on this basis.

Two years later Lindsay (122) described two more cases. In the first, a ruptured saccule was noted, the only mention of the endolymphatic duct being that a few rugae were present in Sinus II and that the fluid showed an affinity for the eosin stain. In the second case, there was a dilated medial portion of the *aqueductus endolymphaticus* (Sinus II) He felt that the histologic appearance of the epithelium and surrounding connective tissue was normal. He concluded on the basis of these findings and his as yet unpublished monkey experiments (21), that the endolymphatic sac and Sinus II were not essential for maintenance of the normal quantity of endolymph.

After Lindsay's reports (118 121 122) regarding the insignificant role of the endolymphatic sac in the pathogenesis of clinical endolymphatic hydrops in man, despite the histopathologic changes which he himself found, there ensued a loss of interest in the histology and the role of the endolymphatic sac in endolymphatic hydrops, with the single exception of Cawthorne (122) until the renaissance in interest previously described.

Then, in 1947 Arnvig (123) described a long standing case in which the endolymphatic duct and sac were found in only a few sections. Many trabeculae and notches were found, and a homogeneous eosin stain was present. The perisaccular connective tissue was dense and

fibrous On the opposite side, the perisaccular connective tissue appeared normal In the duct, there was a small fibroma which projected half way into the lumen (non-obstructive lesion) Arnvig, like his contemporaries concluded that " it will be hardly justifiable to attach any etiologic significance to the fibroma in the endolymphatic duct. The same applies to the difference in structure of the perisaccular connective tissue on the two sides"

Cawthorne (124) noted bilateral absence of the loose perisaccular connective tissue In addition, the epithelium was backed by dense fibrous connective tissue lining the bony wall He felt that this was an obstructive distention of the endolymph system based on previous measurements of osmotic pressures of labyrinthine fluids (Aldred) This was the last definite and positive interest, expressed in the literature, regarding the histopathology of the endolymphatic sac in the human until Shambaugh (38) studied the slide collection of Lindsay s cases (118 121–122 125 127–129) at the University of Chicago in 1966 and observed vascular changes in the sac wall Despite Cawthorne s reaffirmation of the significance of the perisaccular fibrosis he found, his contemporaries continued to discount similar observations

Brunner (130) reported two cases of endolymphatic hydrops The first case was a patient with neurosyphilis and not Ménière s disease, in which the endolymphatic duct was dilated and contained a granular exudate The epithelium was coarse and edematous The second patient, who was found at autopsy to have a chronic hydrocephalus and an osteitis deformans, had a slightly dilated endolymphatic duct surrounded by a firm connective tissue On the opposite side there was a slight dilatation of the endolymphatic duct at its junction with the saccule Otherwise the duct was normal and, like the sac, was surrounded by firm connective tissue There was an exudate in the endolymphatic duct Brunner concluded regarding these findings, that perisaccular fibrosis was not a tenable etiology for endolymphatic hydrops because it was found in temporal bones without hydrolabyrinth and because of the results of Lindsay s (63) obliteration studies of the endolymphatic sac in monkeys

Nager (130) found perisaccular fibrosis in one patient but did not consider it a typical or regular finding in Ménière s disease. At necropsy this patient was found to have an internal hydrocephalus. The left endolymphatic duct was surrounded by fibrous tissue at the internal aperture. There was a papillary epithelial proliferation of the intraosseous portion. The sac reached far into the intradural part. In the lumen were cellular elements and thickened endolymph. The subepithelial connective tissue of the endolymphatic sac was unchanged On the right side the endolymphatic duct had rugae with high epithelium light perisaccular fibrosis and decreased vessels. There was an early neurinoma of the modiolus.

Day & Lindsay (125) reported findings in a patient who had undergone a diathermy (Day) procedure seven years prior to death, but they described no abnormalities of the endolymphatic sac or any difference between sides No statement was made regarding the role of the endolymphatic sac.

Lempert, et al (109) showed photomicrographs of a case of Ménière s disease which was apparently not reported previously as a case of Ménière s disease, although the bones were studied in 1937–38 by Wolff This case was previously reported as a case of hydrops associated with otosclerosis (126) No significant clinical history was given nor was any statement made regarding the histology or role of the endolymphatic sac. Epithelial vesiculation was noted and felt to be related to a chronic progressive herpetic neuritis of the vestibular labyrinth

Hallpike & Harrison (28, 132) reported a case of a patient who died in the early post operative period following a Portmann procedure. However at autopsy the posterior surface of the dura was stripped therefore no

description of the endolymphatic sac was possible.

Lindsay & Schuthess (128) reported a case of endolymphatic hydrops without any clinical or histologic evidence of vestibular dysfunc tion no description of the endolymphatic sac was included

Lawrence & McCabe (133) described a case in which the patient died of cardiac arrest after a destructive labyrinthectomy They reported a normal endolymphatic duct, but the endolymphatic sac was stripped away with the dura at autopsy

Kristensen (135–136) reported two cases of Ménière s disease. In the first case, a direct opening was found between the saccus and the utricule. No other statement was made regarding the endolymphatic sac or duct in either case. Likewise, Schuknecht et al. (136–138) described three cases in which the description and role of the endolymphatic sac was not given.

Altmann & Kornfeld in 1965 (139) reviewed most of the previously reported histopathologic cases of Ménière s disease and reported an additional three cases. In 1968 Altmann & Zechner (120) re-evaluated their cases previously reported in 1965 (139) and made somewhat different observations regarding the endolymphatic sac. The following is a statement for each case of the 1965 observations, followed immediately by the 1968 re evaluation. Their first case showed slightly dilated proximal endolymphatic duct. There was a coarse brownish pigment (Turnbull positive) found in the macrophages of the per iductal connective tissue. There was no endolymphatic sac in the sections. In 1965 no statement of function was made regarding this case. In 1968, they (1 0) re-evaluated this case (Case 1) and found diminution of rugae and perisaccular fibrosis bilaterally In the second case, the endolymphatic duct showed no folds but was of normal width. Cells containing brownish pigment were found in the subepi thelial tissue The distal part of the duct was slightly dilated. The endolymphatic sac showed no pathological changes. Otosclerosis (red) was noted. In 1968 (120) with unilateral disease, no significant differences were noted between the two sides. The third case was originally re ported as having a normal endolymphatic sac and duct. Bilateral otosclerosis was also noted. In the 1968 (120) re-evaluation they described a marked perisaccular fibrosis and almost complete absence of the rugae on the diseased side. The unaffected side was not available for comparison.

Buchs (140) stated that the endolymphatic sac and duct were normal in a three day old premature infant who had histologic endolymphatic hydrops.

Gussen (108) reported a marked bilateral distention of the saccule, endolymphatic sac and endolymphatic duct in a patient with an "inherited" sensorineural hearing loss but no other clinical symptoms consistent with Ménière s disease. The cochlear duct, utricle and semicircular canals were of normal caliber Numerous vesicles were present in the epithe lium of the saccule, semicircular canals and endolymphatic sac and duct. This vesiculation and basement membrane changes were felt to be consistent with movements of large amounts of fluid across the membranes (pinocytosis) and not related to herpetic vesicles as suggested by Lempert, et al (109)

Lindsay et al. (141) in 1967 reported another case of endolymphatic hydrops with a *clinical history consistent with Ménière s disease* but they did not describe the duct or sac. Lindsay (65) later summarized the observations of 13 temporal bones from 10 patients with idiopathic hydrops in the University of Chicago collection and again made the following general statement regarding changes in the endolymphatic sac: no firm conclusions on perisaccular fibrosis [can be made], partly be cause of variations in the state of soft tissue structures after processing

Schuknecht (142) described three further cases. In the ductus reuniens of the first case, he found a papillary structure covered by the

fibrous. On the opposite side, the perisaccular connective tissue appeared normal In the duct, there was a small fibroma which projected half way into the lumen (non-obstructive le sion) Arnvig, like his contemporaries concluded that " *it will be hardly justifiable to attach any etiologic significance to the* fibroma in the endolymphatic duct. The same applies to the difference in structure of the perisaccular connective tissue on the two sides"

Cawthorne (124) *noted bilateral absence of* the loose perisaccular connective tissue In addition the epithelium was backed by dense fibrous connective tissue lining the bony wall. He felt that this was an obstructive distention of the endolymph system based on previous measurements of osmotic pressures of labyrinthine fluids (Aldred) This was the last definite and positive interest, expressed in the literature, regarding the histopathology of the endolymphatic sac in the human until Shambaugh (38) studied the slide collection of Lindsay s cases *(118 121–122 125 127–129)* at the University of Chicago in 1966 and observed vascular changes in the sac wall Despite Cawthorne s reaffirmation of the significance of the perisaccular fibrosis he found his contemporaries continued to discount similar observations.

Brunner (130) reported *two cases of endo*lymphatic hydrops. The first case was a patient with neurosyphilis, and not Ménière s disease, in which the endolymphatic duct was dilated and contained a granular exudate The epithelium was coarse and edematous. The second patient, who was found at autopsy to have a *chronic hydrocephalus and an osteitis de* formans, had a slightly dilated endolymphatic duct surrounded by a firm connective tissue On the opposite side there was a slight dilatation of the endolymphatic duct at its junction with the saccule Otherwise the duct was normal and, like the sac was surrounded by firm connective *tissue There was an exudate in the* endolymphatic duct Brunner concluded, regarding these findings, *that perisaccular* fibrosis was not a tenable etiology for endolymphatic hydrops because it was found in temporal bones without hydrolabyrinth and because of the results of Lindsay s (63) oblitera*tion studies of the endolymphatic* sac in monkeys.

Nager (130) found perisaccular fibrosis in one patient but did not consider it a typical or regular finding in Ménière s disease At necropsy this patient was *found to have an* internal hydrocephalus The left endolymphatic *duct was surrounded by fibrous* tissue at the internal aperture There was a papillary epithelial proliferation of the intraosseous portion. The sac reached far into the intradural part In the lumen were cellular elements and thickened endolymph The subepithelial connective tissue of the endolymphatic sac was unchanged On the right side the endolymphatic duct had rugae with high epithelium light perisaccular fibrosis and decreased vessels. There was an early neurinoma of the modiolus.

Day & Lindsay (125) reported findings in *a patient who* had undergone a diathermy (Day) procedure seven years prior to death, but they described no abnormalities of *the en*dolymphatic sac or any difference between sides No statement was made regarding the role of the endolymphatic sac

Lempert, et al (109) showed photomicrographs of a case of Ménière s disease which was apparently not reported previously as a case of *Ménière s disease although the* bones were studied in 1937–38 by Wolff This case was previously reported as a case of hydrops associated with otosclerosis (126) No significant clinical history was given, nor was *any statement made regarding* the histology or role of the endolymphatic sac. Epithelial vesiculation was noted *and felt to be related* to a chronic progressive herpetic neuritis of the vestibular labyrinth.

Hallpike & Harrison (28, 132) reported a case of a patient who died in the early post operative period following a Portmann procedure. However at autopsy the posterior sur*face of the dura* was stripped therefore, no

in the duct and sac without bony obliteration.

Black et al. (144) reported a case of endolymphatic hydrops associated with bilateral otosclerotic foci, both of which were diagnosed ante-mortem. Bilaterally the vestibular aqueduct and endolymphatic duct were abnormally shortened and had a straightened course, forming a 90 angle with the posterior surface of the petrous pyramid. The distal (dural or smooth portion) endolymphatic sac was absent, but thorough evaluation was impossible because of cutting artifact and post-mortem degeneration. Significantly however they report the absence, bilaterally of the rugose portion of the endolymphatic sac and considered these findings abnormal, striking, and speculative regarding causation of endolymphatic hydrops. They raised the interesting question of developmental arrest of the endolymphatic sac- i.e. some blockage in the development of the course of the vestibular aqueduct, from straight in fetal life, to curved in the adult.

There have been, however histologic case reports of patients with Ménière's disease who did not have cochlear hydrops. Of the three cases reported by Berggren (193) a normal endolymphatic sac was reported in one, and no mention was made of the status of the sac in the other two

With these two recent reports by Altmann & Zechner (120) and Black et al (144) the endolymphatic sac again comes to the fore in the discussion of the pathogenesis of endolymphatic hydrops, although it has been a much neglected structure.

unicellular layer of cuboidal epithelium similar histologically to choroid plexus. A similar but smaller structure was noted on the opposite side No specific statements were made regard ing the histology of the endolymphatic sac. He did say however that examination of the sac had "failed to reveal any constant change which may be associated with diminished re sorptive function Nonetheless the accumula tion of endolymph must be due to either over secretion or diminished absorption, and in view of Kimura s recent experiments, it seems probable that Ménière s disease is caused by diminished resorptive function of the endolymphatic sac It is also possible that it is caused by oversecretions due to abnormal secretory tissue such as ectopic choroid plexus"

At the International Symposium on Mén ière s Disease in October 1967 Altmann (143) said in a discussion period that after re viewing cases of 10 patients with Ménière s disease, his observations confirm the fact that there is no apparent connection between the appearance of the perisaccular tissue and endolymphatic hydrops. In some patients with hydrops, one finds loose perisaccular tissue, and on the other hand, in patients without hy drops, marked fibrosis is found"

In one of Altmann s last papers before his death he & Zechner (120) reported two more cases of endolymphatic hydrops with a re-evaluation of previously reported cases In this paper he apparently changed his attitude regarding the role of the endolymphatic sac in the pathogenesis of endolymphatic hydrops. This reformulated view was essentially like the one originally proposed by Hallpike & Cairns (13 14) They concluded that fibrosis of the perisaccular tissue on the diseased side favored the assumption that disturbances in the absorption of the endolymph in the area could play a role in producing the hydrops

In the first new case (120) there was fibrosis of the tunica propria of the pars rugosa on the affected (right) side. The sinus of the endolymphatic duct showed a normal width The isthmus was slightly narrower than on the other side The epithelium was normal The proximal portion of the lumen contained homogeneous eosinophilic masses. The peripheral layers of the connective tissue surrounding the distal portion of the isthmus were dense. The pars rugosa of the endolymphatic sac was shorter than on the other side it showed a narrow lumen which was lined with cuboidal epithe lium and contained a small amount of pink staining masses there were only a few folds in the wall The surrounding connective tissue was dense and very poorly vascularized particular ly in the distal portion of the pars rugosa Due to the shortness of the latter the terminal part of the endolymphatic sac extented further up into the bone than on the other side. The rugae were absent the surrounding connective tissue was fibrotic and almost avascular The intradural portion of the sac showed a narrow lu men lined with low cuboidal epithelium Within the surrounding connective tissue circum scribed areas of hyalinization were noted On the left side, the duct and sac showed a wider lumen than on the right (affected) side the folds in the pars rugosa were well-developed the surrounding connective tissue was loose and better vascularized The lumen was empty except in the distal portion of the sac where it contained a small amount of pink fluid but no cells

The second case (120) was most likely a postinflammatory (predominately) serous laby rinthitis. On the affected side the isthmic por tion of the endolymphatic duct was, for a distance of about 3 mm completely obliterated by newly formed web-like bone The proximal sinus of the endolymphatic duct was narrow The *pars rugosa* had been replaced by dense scar tissue A narrow lumen became recogniz able in the interosseous portion of the sac which was lined with cuboidal epithelium The lumen of the intradural portion of the sac was somewhat wider and filled with homogeneous eosinophilic masses The surrounding subepithelial tissue was markedly fibrotic. The opposite (left) side showed the same changes

in the duct and sac without bony obliteration.

Black et al. (144) reported a case of endolymphatic hydrops associated with bilateral otosclerotic foci, both of which were diagnosed ante-mortem. Bilaterally the vestibular aqueduct and endolymphatic duct were abnormally shortened and had a straightened course, forming a 90° angle with the posterior surface of the petrous pyramid. The distal (dural or smooth portion) endolymphatic sac was absent, but thorough evaluation was impossible because of cutting artifact and post-mortem degeneration. Significantly however they report the absence, bilaterally of the rugose portion of the endolymphatic sac and considered these findings abnormal striking, and speculative regarding causation of endolymphatic hydrops. They raised the interesting question of developmental arrest of the endolymphatic sac i.e. some blockage in the development of the course of the vestibular aqueduct, from straight in fetal life, to curved in the adult.

PREFACE

The study presented here was carried out in 1966–1969 during my appointment as Research Assistant in the Institute of Anatomy and the Department of Otolaryngology University of Aarhus.

I owe a very great debt of gratitude to the late Professor Lárus Einarson, M D for the unfailing interest he took in my investigations and for the ideal working conditions he provided for me during my appointment and later when I came as a guest to the Institute of Anatomy I deeply regret that Professor Einarson did not see the completion of the study before his death.

I wish to express my sincere thanks to my chiefs in the Department of Otolaryngology Professor H C. Andersen, M.D and Dr O Elbrønd, for the excellent working conditions which permitted me not only to complete the study but also to preserve the contact with the clinical work in the department.

I am very grateful to Professor Otto Jepsen, M D who personally secured the biopsy specimens and gave me invaluable support and encouragement during the study

It is a pleasure for me to acknowledge my thanks to my brother-in-law Erik Harsaae Professor of Statistics, University of Aarhus, for his unsparing help in the statistical analysis of the material. He developed the formula for the distribution of DNA-synthetizing cells (Chapter 4 Mitoses)

My thanks are also due to M. F Lilsberg, M D., for his aid, especially during the initial phases of the work. With his wide knowledge, Dr Lilsberg greatly contributed to my understanding of the fundamental histochemical aspects of the investigation.

I am indebted to Jørgen Hastrup, M.D of the Institute of Pathology the University Hospital of Aarhus, who kindly and patiently helped me with the evaluation of the histological sections.

I have received much help from Mrs. Inge Lise Walbovd, Secretary Mrs. Ilse Jensen, Laboratory Technician, and Mr Eigil Eriksen, Conservator I wish to express my thanks to them and also to all other members of the staff, who through their co-operation and kindness made it a daily pleasure for me to work in the Institute of Anatomy

A. Rousing, M. T F., has assisted me in the preparation of the English version of the manuscript and in the solution of the technical problems involved. I hereby extend my sincere thanks for his assistance.

Last but not least, my gratitude goes to my wife, Birte for her affectionate support and encouragement during all the phases of this investigation.

Odense September 1970

Ole Greisen

CONTENTS

INTRODUCTION

The cellular content of nucleic acids reflects essential aspects of the function of the cell under normal and pathological conditions.

Most previous studies on the nucleic acid content of the bronchial epithelium are sporadic. It was therefore the purpose of this study systematically to investigate the content of nucleic acids in the nuclei and cytoplasm of the bronchial epithelium under normal and various pathological conditions.

The bronchial epithelium is a very suitabl object for such a study as the epithelial tissu occurs in a number of morphologically well defined states which can contribute to the elucidation of the function of the nucleic acid during changes in the morphology of the epithelium.

INTRODUCTION

The cellular content of nucleic acids reflects essential aspects of the function of the cell under normal and pathological conditions.

Most previous studies on the nucleic acid content of the bronchial epithelium are sporadic. It was therefore the purpose of this study systematically to investigate the content of nucleic acids in the nuclei and cytoplasm of the bronchial epithelium under normal and various pathological conditions.

The bronchial epithelium is a very suit object for such a study as the epithelial ti occurs in a number of morphologically w defined states which can contribute to elucidation of the function of the nucleic a during changes in the morphology of the thelium.

NUCLEIC ACIDS

Chemistry

The knowledge of the nucleic acids began with Miescher's investigations (1897) of a material isolated from pus cells which he called "nuclein

The nucleic acids are built up of chains of nucleotides consisting of a nitrogenous base, a carbohydrate and phosphoric acid.

Both ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) contain four different nitrogenous bases. Three of them, viz. the purines adenine and guanine and the pyrimidine cytosine are present both in DNA and RNA, whereas the pyrimidine thymine occurs only in DNA, and the pyrimidine uracil only in RNA. This important difference is utilized in tracer studies, in which DNA can be specifically labelled by radioactive thymidine, and RNA by radioactive uracil.

As far as the carbohydrate is concerned, RNA and DNA differ from each other in that RNA contains ribose, while DNA contains deoxyribose. Deoxyribose gives rise to the specific Feulgen reaction of DNA. In the nucleotide, the combination carbohydrate-base forms a nucleoside

The phosphoric acid binds the nucleotides together by attaching the carbohydrates in two adjacent nucleosides by means of an ester bond. These bonds combine a carbon atom (C 3) in one nucleoside and one (C 5) in the next. In this way two of the three acid groups are used to join together two adjacent molecules of carbohydrate. The last acid group is free for combining with basic groups.

While it was formerly thought that the four bases in the nucleic acids occurred in equal amounts and formed tetranucleotides, it is now realized that the proportions of the bases differ in different species of animals, both as far as DNA and RNA are concerned. The smallest unit in the nucleic acids is the mononucleotide (Chargaff 1955)

In DNA the sum of purines is equal to that of pyrimidines. The ratio of the purine adenine to the pyrimidine thymine, and that of the purine guanine to the pyrimidine cytosine are always equal to one. On the basis of these relations and X-ray diffraction techniques, Watson and Crick advanced their theory of the double-helix structure of the DNA molecule

Each molecule of DNA consists of two long chains of polynucleotides forming a double spiral around a central axis. The nucleotides are arranged in a plane at right angles to the chain of polynucleotides, so that the bases are joined to each other by means of hydrogen bonds, and as the distance between the chains of polynucleotides is constant, so that a base of purine in one chain always combines with a base of pyrimidine in the other Owing to the above-mentioned constant relationship between the bases, adenine will always combine with thymine, and cytosine always with guanine. The chains will thus be complementary to each other The sequence of the four bases in a chain of polynucleotides forms the basis for the genetic information. During the doubling of DNA the two chains become detached from each other and each will act as a template for the synthesis of two complementary chains (DeRobertis et al. 1965)

A DNA molecule is very long. The smallest known chromosome is a single-chained DNA molecule, consisting of 5,500 nucleotides. All other isolated molecules of DNA consist of double chains with molecular weights of the

order of 10^9 The whole chromosome in a known bacteriophage is thus one DNA molecule consisting of a continuous double helix comprising about 200 000 pairs of bases and with molecular weights ranging from 1.2×10^8 to 1.6×10^8 (Perutz 1962)

Certain observations suggest that this perfectly regular structure of the DNA molecule cannot in all cases explain the properties of DNA but that there must be certain variations (Bendich & Rosenkranz 1963)

RNA is built up of a polynucleotide chain but as distinct from DNA with uracil and ribose instead of thymine and deoxyribose RNA is present in the cell in different forms.

Transfer or soluble RNA (t or s RNA) exists in a free form in the cytoplasm t RNA is not one substance, but consists of different molecules with molecular weights of the order of 25 000 which corresponds to a length of the polynucleotide chain of 70–80 nucleotides. t RNA contains small amounts of methylated bases in addition to the usual bases in RNA and also small amounts of 5 ribocyluracil nucleotide, in which uracil is bound to C 1 in ribose by means of C 5 instead of N 3 (Perutz 1962) t RNA usually constitutes 10–25 % of the total RNA content of the cell (Hoagland 1960 Amano 1967 b)

As suggested by the term ribosome RNA (r RNA) is found in the ribosomes bound to protein and constitutes about one half of the ribosomes r RNA in E. coli which has been investigated in some detail constitutes about 63 % of the ribosome (Perutz 1962) and consists of at least two different molecules of RNA with molecular weights of 0 56 and 1.12×10^6 respectively It seems to be a common property for all r RNA to have these two different fractions (Spirin 1964) r RNA consists of one long chain of polynucleotides the small r RNA molecule containing about 1,500–2 000 nucleotides, the large molecule 4 000–4,500 nucleotides (Spirin 1964) r RNA constitutes the greater part of the RNA in the cell usually 75–90 % (Hoagland 1960 Amano 1967 b)

Messenger RNA (m RNA) is present in relatively small amounts It constitutes at most 5–8 % of the total content of RNA in the cell Its molecular weight varies widely possibly according to the variations in the size of the proteins which are synthetized in the cell. The molecular weight varies from 2×10^4 to 2×10^6 or even higher (Spirin 1964)

In contrast to the double-chained DNA molecule, r RNA is a flexible single chain of polynucleotides, twisted in compact particles and capable of making reversible changes in form and dimensions and number of intramolecular hydrogenous bonds depending on ionic strength temperature and pH.

The occurrence of double-helix regions has been demonstrated in ribosome and soluble RNA The double-helix structure of RNA is not complete and perfect as in DNA but partial and with defects, i. e. unpaired bases (Doty et al. 1959 a, 1959 b) These helix regions are only relatively short and formed locally by hydrogenous bonds between the bases in the same chain, which is bent back on itself (Perutz 1962 Spirin 1963) The linkage between the bases in the double-helix regions in DNA occurs between complementary bases, so that purines are bound to pyrimidines. The vast majority of the bonds occur between guanine–cytosine and adenine–uracil

Weighty evidence suggests that t RNA is built up of a single chain of polynucleotides which is bent and forms a double helix with itself Foldings may occur in different places, so that the same chain may have several double helix regions, and the axes in these regions will radiate according to the electrostatic forces (Spirin 1964)

A fact which is in favour of the presence of a double-helix structure in the t RNA molecule is that the ratio between the complementary pairs of bases is close to one. This is, however not the case in r RNA (Perutz 1962) and even though double-helix regions have been demonstrated in the r RNA molecule it must mean that they are not nearly as frequent as in the t RNA molecule.

Localization of Nucleic Acids

All DNA in cells from mammals is localized in the cell nucleus (Dounce 1955 Mirsky & Osawa 1961), but in various lower animals and plants DNA has been demonstrated in the cytoplasm (André 1965 Gahan & Chayen 1965). It cannot be determined with certainty whether the greater part or all DNA in the nucleus is bound to protein (Chargaff 1955) The binding occurs primarily to basic proteins, which in higher animals and plants are histones. In spermatozoa, the basic protein is chiefly protamine (Mirsky & Osawa 1961).

After extraction of the nucleohistones, an additional fraction of protein can be isolated from the chromosomes, viz. residual protein, which is a protein with the iso-electric point in the acid area (Mirsky & Ris 1951).

All DNA in the cell nucleus is localized in the chromosomes (Caspersson 1950 Thorell 1955 Mirsky & Osawa 1961) and it is assumed that each chromosome contains a constant amount of DNA (Patau & Swift 1953) Parallelism between the DNA content in the cell nucleus and the number of chromosomes has been reported by many investigators (Swift 1953 Patau & Swift 1953 Richards et al. 1956 Hauschka et al. 1957 Sandritter et al. 1960, Stich et al. 1960 Sandritter Hilwig et al. 1965 Atkin 1967).

After extraction of the nucleohistones, which consist of about 45 % DNA and about 55 % histone protein, about 10 % of the chromosome mass remains. Of this residual chromosome, the residual protein constitutes about 80 % while the RNA content varies between 7.5 and 14 % and the DNA content is only very slight, from 1.5 to 6 % The proportion between the various components of the residual chromosome seems to vary in isolated chromosomes from different tissues (Thorell 1955).

DNA is not just one definite substance, but is found in various forms depending on the proportion between the nitrogenous bases. In all the animal species studied, adenine–thymine predominate, while the content of guanine–cytosine is higher in certain micro-organisms. DNA from different species differ in the composition of nucleotides, whereas DNA from different organs in the same species has the same composition (Chargaff 1955 Mirsky & Osawa 1961).

The DNA content in the cell nucleus is 9–11 % of the dry weight (Pollister 1952 a, Dounce 1955) As first shown by Boivin, Vendrely & Vendrely (1948) and Mirsky & Ris (1949), and later confirmed by many other investigators, the content of DNA per cell nucleus is constant in a given species.

The DNA content is not only constant in different tissues of the organism, with the exception of the germinative cells, but it is also constant and independent even of great physiological influences in the organism. It is thus constant during prolonged fasting and during dietary alterations (Swift 1953 Kurnick 1955 Leslie 1955 Vendrely 1955 Mirsky & Osawa 1961)

An important biological variation in the DNA content occurs during the preparation for mitosis in the form of synthesis and doubling of the DNA content.

The function of DNA in the cell nucleus may thus be said to be the starting point for the synthesis of more DNA in the preparation for mitosis, and as carrier of the genetic properties. DNA is also of importance in the formation of energy-rich phosphate bonds and in the synthesis of adenosinetriphosphate in the cell. This effect is unspecific and can be replaced by other polynucleotides (Allfrey & Mirsky 1957) Finally the presence of DNA is necessary for the synthesis of RNA, and hence for the synthesis of proteins and enzymes in the entire cell.

RNA is present both in the nucleus and in the cytoplasm. In the cell nucleus, about 25 % of the nuclear RNA is found in the nucleolus, the rest in the nuclear sap and in the chromosomes (Amano 1967 a, 1967 b) Most of the RNA content in the cell, about 90 % is found in the cytoplasm, a little is free, but the greater

part is bound in the ribosomes, which in the nerve cells, for example, form the Nissl substance.

After his introduction of the specific staining of the nucleic acids in nerve cells with gallocyanin-chromalum, Einarson (1932) showed that the Nissl substance contained nuclear chromatin substances. He also demonstrated that this substance was formed within the nucleus and diffused through the nuclear membrane (Einarson 1933 1935) and that the Nissl substance consisted of three components viz. a basophilic chromatin substance, a basophilic protein and an acidophilic protein.

That this cytoplasmic basophilic substance, which did not yield the Feulgen reaction, was a nucleic acid (RNA) was later confirmed by several investigators (Caspersson & Schultz 1939 Landström Caspersson & Wolfart 1941 Brachet 1941 Hydén 1943)

The nucleus has an important function in the formation of all types of RNA. Labelling with radioactive substances, which were incorporated during the synthesis of RNA seemed to show that by far the greater part of RNA was formed inside the cell nucleus, but that some formation probably also took place in the cytoplasm (Brachet 1961 Smellie 1963) However other investigators (Taylor 1960 Scholtissek 1966) have shown that all RNA is apparently formed inside the cell nucleus and from here diffuses into the cytoplasm

r RNA is synthetized in the nucleus across the DNA molecule, and probably accumulates in the nucleolus which is formed near the chromocentre (Caspersson 1950) From here it diffuses into the cytoplasm, where it is bound to the proteins in the ribosomes. Electron-microscopic studies have shown that particles of a similar size and structure are present in the nucleus, especially *near the nuclear membrane* and around the nucleolus, and probably derived from the latter (DeRobertis 1956) Chemical *analysis of isolated* nucleoli has revealed a RNA content of the order 2–4 % (Nurnberger et al. 1952, Vincent 1955 Dounce 1955) while Amano (1967 a) reported a RNA content of 13 9 % in nucleoli. A possible source of error in measuring the RNA content in isolated nucleoli is the loss of RNA during isolation. Cytophotometric studies of nucleoli of plant cells at prophase showed a higher content of RNA in the nucleoli (Pollister & Leuchtenberger 1949) but certain objections has been raised against these studies (Dounce 1955)

The ribosomes are nucleoproteins consisting of 40–65 % RNA and 60–35 % protein. The ribosomes are found in all types of cells in all organs without exception (Spirin 1964)

m-RNA is synthetized across the DNA molecule and is complementary to part of one of the chains in the DNA molecule, with the only difference that thymine in DNA is replaced by uracil in m-RNA. It migrates through the nuclear membrane and become attached to the ribosomes. Only bound to them is it able to participate in the synthesis of protein The specificity of the protein which is synthetized depends on the type of m RNA which is attached to the ribosome However r RNA cannot function as a polynucleotide template unless the third type of RNA s-RNA is present in the ribosome One specific s-RNA molecule corresponds to each amino acid. Only when the specific amino acid is attached to s-RNA is it able to participate in the synthesis of proteins which occurs in the ribosomes. In each s-RNA molecule there is a part of the nucleotide chain which is complementary to a part of the polynucleotide chain in m RNA *s RNA is the substance* which translates the code of polynucleotides in m-RNA into that of amino acids, and in this *way it determines the sequence of amino acids* in the protein (Spirin 1964) The synthesis of *proteins thus* occurs in the ribosomes by a complicated interaction between the three different kinds of cytoplasmic RNA. s-RNA constitutes about 25 % of the cytoplasmic RNA and about one third of the RNA content of the cell nucleus (Amano 1967 a, 1967 b)

Unlike DNA RNA is not species-specific, but varies as much in composition in differe

members of the same species as in members of different species (Magasanik 1955)

The RNA content per cell nucleus varies considerably in different organs from the same species of animal, as contrasted with the constant content of DNA. Determined by chemical methods, nuclear RNA usually constitutes 7.5–11 % of the total RNA content of the cell (Swift 1953 Mirsky & Osawa 1961) The ratio of RNA to DNA in the cell nucleus varies according to the organ examined and the animal concerned—from 1 3.5 in rat-liver nuclei to 1 17 in calf thymus nuclei (Swift 1953 Dounce 1955)

The RNA content shows considerable fluctuations in cells which undergo changes in mitotic activity differentiation and protein synthesis (Swift 1966 a). During fasting, a considerable reduction in the nuclear content of RNA occurs, while increased mitotic activity tends to increase the content.

Any cell with great synthesis of protein is characterized by a high content of RNA both in the nucleus and in the cytoplasm (Caspersson 1941 Brachet 1941). Thus, this applies to growing cells, and to cells with great activity such as nerve cells and secreting cells (Caspersson 1947)

As shown by Einarson and his coworkers, there is a relation between the functional and pathological activity of nerve cells and their content of nucleic acid (Einarson 1933 1935 1937 1945 1949 a, 1949 b, 1957 Einarson & Lorentzen 1946, Einarson & Krogh 1955 Lorentzen 1950, Bech 1957 Pakkenberg 1960).

The relation between the secretory activity in a cell and its *cytoplasmic basophilic substance* was shown by means of staining with gallocyanin-chromalum in tissues from the pancreas (Oram 1955) the stomach (Weber 1958) and the serous salivary glands (Holtet 1962).

Demonstration of Nucleic Acids

In the demonstration of nucleic acids in situ in histological sections various properties of the nucleic acids are utilized, conditioned by their components of phosphoric acid, carbohydrate and nitrogenous bases.

The demonstration of nucleic acids with basic stains depends on the binding of the stains to the strongly acid groups of phosphate which are liberated by treating the tissues with the stain or fixative (Sandritter 1955 Kurnick 1955 Einarson 1960) The nucleic acids in the cell is linked to protein by phosphate bonds, and the disengagement of these linkages requires a certain time depending on the hydrogen-ion concentration (Lisberg 1962, 1963) Using a number of basic stains with pH levels below 2, Lisberg (1962 1963) found that the staining intensity is proportional to the staining time until the staining intensity reaches a maximum after 24–48 hours. For gallocyanin-chromalum, it has been shown experimentally that the staining intensity in nervous tissue reaches the maximum in the course of 14–16 hours (Pakkenberg 1958). This progressivity of gallocyanin-chromalum staining was emphasized by Einarson right from his earliest works on this staining method (1932, 1933 1934 1935 1951).

In studies on the Nissl substance in nerve cells, Einarson showed that RNA in the cytoplasm was bound to a basic and an acid protein. Mirsky & Ris (1951) found that DNA in the cell nucleus was bound both to basic proteins, histones, and to a strongly acid protein, which they called residual protein. The staining capacity of this acid protein was studied in detail by Lisberg (1963) who found that, both in the cytoplasm and the cell nucleus, it was stained with basic dyes down to a pH of 3–4.6.

A large number of basic stains have been used for the demonstration of nucleic acids, but with few exceptions (Lisberg 1962), no regard was paid to the pH of the staining solution. Specific staining of nucleic acids can be obtained only by stains which are on the acid side of the iso-electric point of the proteins, i. e. at a pH below 2.

Both DNA and RNA stain with basic dyes

part is bound in the ribosomes, which in the nerve cells, for example, form the Nissl substance.

After his introduction of the specific staining of the nucleic acids in nerve cells with gallocyanin-chromalum Einarson (1932) showed that the Nissl substance contained nuclear chromatin substances. He also demonstrated that this substance was formed within the nucleus and diffused through the nuclear membrane (Einarson 1933 1935) and that the Nissl substance consisted of three components viz. a basophilic chromatin substance, a basophilic protein and an acidophilic protein.

That this cytoplasmic basophilic substance, which did not yield the Feulgen reaction, was a nucleic acid (RNA) was later confirmed by several investigators (Caspersson & Schultz 1939 Landström Caspersson & Wolfart 1941 Brachet 1941 Hydén 1943)

The nucleus has an important function in the formation of all types of RNA Labelling with radioactive substances, which were incorporated during the synthesis of RNA seemed to show that by far the greater part of RNA was formed inside the cell nucleus, but that some formation probably also took place in the cytoplasm (Brachet 1961 Smellie 1963) However other investigators (Taylor 1960 Scholtissek 1966) have shown that all RNA is apparently formed inside the cell nucleus and from here diffuses into the cytoplasm

r RNA is synthetized in the nucleus across the DNA molecule, and probably accumulates in the nucleolus which is formed near the chromocentre (Caspersson 1950) From here it diffuses into the cytoplasm where it is bound to the proteins in the ribosomes. Electron microscopic studies have shown that particles of a similar size and structure are present in the nucleus, especially near the nuclear membrane and around the nucleolus, and probably derived from the latter (DeRobertis 1956) Chemical analysis of isolated nucleoli has revealed a RNA content of the order 2–4 % (Nurnberger et al. 1952 Vincent 1955 Dounce 1955) while Amano (1967 a) reported a RNA content of 13 9 % in nucleoli. A possible source of error in measuring the RNA content in isolated nucleoli is the loss of RNA during isolation. Cytophotometric studies of nucleoli of plant cells at prophase showed a higher content of RNA in the nucleoli (Pollister & Leuchtenberger 1949) but certain objections has been raised against these studies (Dounce 1955)

The ribosomes are nucleoproteins consisting of 40–65 % RNA and 60–35 % protein. The ribosomes are found in all types of cells in all organs without exception (Spirin 1964)

m RNA is synthetized across the DNA molecule and is complementary to part of one of the chains in the DNA molecule, with the only difference that thymine in DNA is replaced by uracil in m RNA. It migrates through the nuclear membrane and become attached to the ribosomes. Only bound to them is it able to participate in the synthesis of protein The specificity of the protein which is synthetized depends on the type of m-RNA which is attached to the ribosome. However r RNA cannot function as a polynucleotide template unless the third type of RNA s-RNA is present in the ribosome. One specific s RNA molecule corresponds to each amino acid. Only when the specific amino acid is attached to s RNA is it able to participate in the synthesis of proteins which occurs in the ribosomes. In each s-RNA molecule there is a part of the nucleotide chain which is complementary to a part of the polynucleotide chain in m-RNA s RNA is the substance which translates the code of polynucleotides in m RNA into that of amino acids, and in this way it determines the sequence of amino acids in the protein (Spirin 1964) The synthesis of proteins thus occurs in the ribosomes by a complicated interaction between the three different kinds of cytoplasmic RNA. s RNA constitutes about 25 % of the cytoplasmic RNA and about one third of the RNA content of the cell nucleus (Amano 1967 a, 1967 b)

Unlike DNA RNA is not species-specific, but varies as much in composition in different

members of the same species as in members of different species (Magasanik 1955)

The RNA content per cell nucleus varies considerably in different organs from the same species of animal, as contrasted with the con stant content of DNA. Determined by chemical methods, nuclear RNA usually constitutes 7.5–11 % of the total RNA content of the cell (Swift 1953 Mirsky & Osawa 1961). The ratio of RNA to DNA in the cell nucleus varies according to the organ examined and the animal concerned—from 1 3.5 in rat-liver nuclei to 1 17 in calf thymus nuclei (Swift 1953 Dounce 1955)

The RNA content shows considerable fluc tuations in cells which undergo changes in mitotic activity differentiation and protein synthesis (Swift 1966 a). During fasting, a consider able reduction in the nuclear content of RNA occurs, while increased mitotic activity tends to increase the content.

Any cell with great synthesis of protein is characterized by a high content of RNA both in the nucleus and in the cytoplasm (Caspersson 1941 Brachet 1941). Thus this applies to growing cells, and to cells with great activity such as nerve cells and secreting cells (Caspersson 1947).

As shown by Einarson and his coworkers, there is a relation between the functional and pathological activity of nerve cells and their content of nucleic acid (Einarson 1933 1935 1937 1945 1949 a, 1949 b 1957 Einarson & Lorentzen 1946, Einarson & Krogh 1955 Lorentzen 1950, Bech 1957 Pakkenberg 1960).

The relation between the secretory activity in a cell and its cytoplasmic basophilic substance was shown by means of staining with gallocyanin-chromalum in tissues from the pancreas (Oram 1955) the stomach (Weber 1958) and the serous salivary glands (Holtet 196)

Demonstration of Nucleic Acids

In the demonstration of nucleic acids in situ in histological sections various properties of the nucleic acids are utilized, conditioned by their components of phosphoric acid, carbohydrate and nitrogenous bases.

The demonstration of nucleic acids with basic stains depends on the binding of the stains to the strongly acid groups of phosphate which are liberated by treating the tissues with the stain or fixative (Sandritter 1955 Kurnick 1955 Einarson 1960) The nucleic acids in the cell is linked to protein by phosphate bonds, and the disengagement of these linkages requires a certain time depending on the hydrogen-ion concentration (Liisberg 1962, 1963). Using a number of basic stains with pH levels below 2, Liisberg (1962, 1963) found that the staining intensity is proportional to the staining time until the staining intensity reaches a maximum after 24–48 hours. For gallocyanin-chromalum, it has been shown experimentally that the staining intensity in nervous tissue reaches the maximum in the course of 14–16 hours (Pakkenberg 1958). This progressivity of gallocyanin-chromalum staining was emphasized by Einarson right from his earliest works on this staining method (1932, 1933 1934 1935 1951)

In studies on the Nissl substance in nerve cells, Einarson showed that RNA in the cytoplasm was bound to a basic and an acid protein. Mirsky & Ris (1951) found that DNA in the cell nucleus was bound both to basic proteins, histones, and to a strongly acid protein, which they called residual protein. The staining capacity of this acid protein was studied *in detail* by Liisberg (1963), who found that, both in the cytoplasm and the cell nucleus, it was stained with basic dyes down to a pH of 3–.6.

A large number of basic stains have been used for the demonstration of nucleic acids, but with few exceptions (Liisberg 1962), no regard was paid to the pH of the staining solution. Specific staining of nucleic acids can be obtained only by stains which are on the acid side of the iso-electric point of the proteins, i.e at a pH below 2.

Both DNA and RNA stain with basic dyes.

A certain differentiation can be obtained with methyl green, which stains DNA, and pyronin which stains RNA. The difference in staining of the nucleic acids with methyl green–pyronin is due to differences in the degree of polymerization of DNA and RNA (Kurnick 1955).

With the Feulgen staining DNA can be specifically demonstrated. The specificity is conditioned by the carbohydrate part. The reaction is caused by aldehyde groups which are liberated from deoxyribose in DNA by acid hydrolysis. The reaction can be regarded as a specific qualitative demonstration of DNA. The staining intensity depends on the time of hydrolysis, as a certain liberation and wash-out of DNA occur during the hydrolysis (Kurnick 1955) and it also depends on the fixative used. Finally the tissue may contain other available aldehydes which stain with Schiff's reagent. However, under well-defined experimental conditions and with well-defined hydrolysis times, Feulgen staining does give reproducible values, and it has been used by a large number of investigators for semi-quantitative determinations of the DNA content in cell nuclei.

As shown by Caspersson (1936) the nucleic acids absorb ultraviolet light with an absorption maximum at 2600 A. The specific absorption is due to the heterocyclic nitrogenous purine and pyrimidine bases. Determination of the nucleic acid content by this method requires, however, a complicated and costly equipment.

For relative-quantitative determinations in situ, photometric methods must be used. Here it must be required that the absorbing material is specific for nucleic acids, that the material is suitable for photometry and when stained tissue is used, that the binding of the stain is stoicheiometrical.

Gallocyanin-chromalum

Staining with gallocyanin-chromalum has been used for the determination of the content of nucleic acid in nerve cells under various physiological and pathological conditions (Einarson 1932, 1933, 1935, 1937, 1945, 1949 a, 1949 b, Einarson & Lorentzen 1946, Lorentzen 1950, Einarson & Krogh 1955, Bech 1957, Einarson & Telford 1960). The method has also been used for the determination of the content of nucleic acids in the secretory cells of the pancreas (Oram 1955), the stomach (Weber 1958) and the serous salivary glands (Holtet 1962), as well as in the epithelial cells in the prostate (Jacobsen 1968). Among a large number of other investigators who have employed gallocyanin-chromalum staining may also be mentioned Lagerstedt (1949), Grundmann et al. (1961 b), Dahlgren (1964), Haddad (1968 a), Pakkenberg, and Sandritter and his coworkers.

The theoretical background for the use of gallocyanin-chromalum is briefly as follows.

Gallocyanin, which is an oxazine dye, combines with the metal salt chromalum to a complex compound, a lake, which has a positive charge. This positively charged lake is adsorbed on the negatively charged phosphate groups in the nucleic acids and forms a stable chemical compound with these. Binding to the phosphoric acid in the nucleic acids occurs (Einarson 1951, Lilsberg 1962, 1968). The staining is progressive, i. e. the dye is bound to anions in the tissue until there are no more free negative groups available, after which the staining intensity will not increase. The binding is so stable that the staining is not influenced by alcohol or xylol during the dehydration, or mounting (Einarson 1951, Lilsberg 1962). The staining is not changed by storage for a long time or by exposure to light (Einarson 1934, Oram 1955, Kasten et al. 1962, Sandritter et al. 1963).

The pH in the gallocyanin-chromalum solution is 1.64, i. e. far on the acid side of the iso-electric point of the proteins. At this pH the proteins will have positive charges and will therefore be unable to bind the positively charged dye lake. The only possible explanation of the binding of the stain is linkage of the positive lake cation to negative groups in the strong mineral acids, i. e. the phosphoric acid in the nucleic acids (Lilsberg 1962).

The very weak unspecific co-staining of the tissue which can be seen is probably due to absorption of the basic $(CH_3)_3N$ groups in the dye, the lake sulphate (Einarson 1951) At the low pH the co-staining is without significance, but it increases with higher pH

The strong, deep-blue colour with gallocyanin-chromalum is specific for nucleic acids. The specificity is confirmed by the good agreement which is found between measurements of the nucleic acid content by means of absorption of ultraviolet light and the gallocyanin-chromalum staining (Lagerstedt 1949 Sandritter 1955 Sandritter et al. 1957 Kiefer et al. 1967).

The specificity has also been confirmed by ribonuclease (RNase) experiments. After RNase treatment of nervous tissue it was shown that it was not possible to stain the Nisal substance with gallocyanin-chromalum (Sandritter 1955 Bech 1957 Sandritter et al. 1957 Schümmelfeder et al. 1958 Pakkenberg 1958, Linberg 196.., Goncalves & Haddad (in press), Haddad 1968 a)

Electron microscopic studies have further confirmed the specificity of gallocyanin-chromalum for nucleic acids in yeast cells (Mundkur 1961 1964).

According to the staining theory gallocyanin-chromalum is linked to the strongly acid phosphate groups of the nucleic acids. The proteins are not dissociated, as the only groups which can have a negative charge at this low pH (pH 1 64) are the strong mineral acids. In agreement with this, it can be expected that linkage to other strongly acid groups in the tissues may occur and it has in fact been shown that acid mucopolysaccharides will stain (Sandritter 1955 Schümmelfeder et al. 1958 Linsberg 196.. Haddad 1968 a, b) However it is a characteristic feature that the staining cannot be removed by treatment with RNase and that it is unmistakably metachromatic in the red area, which at the low pH indicates mucin sulphate (Curran 1964) Furthermore, mucin is PAS-positive and can be eliminated a a source of error by its localization and the morphology of the tissue (e. g. in the goblet cells of the bronchial epithelium)

With the above-mentioned reservation, the staining of the nucleic acids with gallocyanin-chromalum is specific, and the blue orthochromatic staining of the nucleic acids is, without reservation, specific for them.

The condition for using a dye for quantitative histochemical determinations is that Beer Lambert s low applies to it, i. e. that the extinction is proportional to the concentration and the thickness of the absorbing substance. That the binding of gallocyanin-chromalum to the nucleic acids is progressive and quantitative was emphasized by Einarson (1947 1951).

Lambert s law which says that the extinction is proportional to the thickness, is valid for nucleic acid-bound gallocyanin-chromalum both in vitro and in histological sections (Diefenbach & Sandritter 1954 Sandritter et al. 1954 Pakkenberg 1958, Sandritter Kiefer & Rick 1963 1966).

Beer's law (the extinction is proportional to the concentration) has been shown for gallocyanin-chromalum in vitro (Diefenbach & Sandritter 1954 Sandritter et al. 1954 Sandritter et al. 1963) In histological sections, Beer's law can be proved only indirectly (Kasten 1958) by the absorption curve being the same for tissue-bound gallocyanin-chromalum in nuclei with different extinctions. Gallocyanin-chromalum also fulfils this requirement (Diefenbach & Sandritter 1954 Sandritter et al. 1963) That gallocyanin-chromalum is linked stoicheiometrically to nucleic acids in tissues was shown by Jobst & Sandritter (1961 1964) and by Kiefer et al. (1967)

It thus appears that Beer Lambert s law is valid for gallocyanin-chromalum linked to nucleic acids, both in vitro and tissue-bound in histological sections.

Ribonuclease

RNase was introduced in histology by Brachet (1940) This enzyme is widely used in testing

A certain differentiation can be obtained with methyl green, which stains DNA, and pyronin, which stains RNA The difference in staining of the nucleic acids with methyl green–pyronin is due to differences in the degree of polymer ization of DNA and RNA (Kurnick 1955)

With the Feulgen staining DNA can be spe cifically demonstrated The specificity is conditioned by the carbohydrate part. The reaction is caused by aldehyde groups which are liber ated from deoxyribose in DNA by acid hydrolysis. The reaction can be regarded as a specific qualitative demonstration of DNA. The stain ing intensity depends on the time of hydrolysis, as a certain liberation and wash-out of DNA occur during the hydrolysis (Kurnick 1955) and it also depends on the fixative used. Finally the tissue may contain other available aldehydes which stain with Schiff's reagent. How ever under well-defined experimental condi tions and with well-defined hydrolysis times, Feulgen staining does give reproducible values, and it has been used by a large number of investigators for semi-quantitative determina tions of the DNA content in cell nuclei

As shown by Caspersson (1936) the nucleic acids absorb ultraviolet light with an absorption maximum at 2600 Å The specific absorption is due to the heterocyclic nitrogenous purine and pyrimidine bases. Determination of the nucleic acid content by this method requires, however a complicated and costly equipment.

For relative-quantitative determinations in situ photometric methods must be used Here it must be required that the absorbing ma terial is specific for nucleic acids, that the material is suitable for photometry and, when stained tissue is used, that the binding of the stain is stoicheiometrical

Gallocyanin-chromalum

Staining with gallocyanin-chromalum has been used for the determination of the content of nucleic acid in nerve cells under various phy siological and pathological conditions (Einarson 1932, 1933 1935 1937 1945 1949 a, 1949 b Einarson & Lorentzen 1946 Lorentzen 1950 Einarson & Krogh 1955 Bech 1957 Einarson & Telford 1960) The method has also been used for the determination of the content of nucleic acids in the secretory cells of the pancreas (Oram 1955) the stomach (Weber 1958) and the serous salivary glands (Holtet 1962) as well as in the epithelial cells in the prostate (Jacobsen 1968) Among a large num ber of other investigators who have employed gallocyanin-chromalum staining may also be mentioned Lagerstedt (1949) Grundmann et al. (1961 b) Dahlgren (1964) Haddad (1968 a) Pakkenberg, and Sandritter and his coworkers.

The theoretical background for the use of gallocyanin-chromalum is briefly as follows.

Gallocyanin, which is an oxazine dye, combines with the metal salt chromalum to a com plex compound a lake, which has a positive charge. This positively charged lake is ad sorbed on the negatively charged phosphate groups in the nucleic acids and forms a stable chemical compound with these. Binding to the phosphoric acid in the nucleic acids occurs (Einarson 1951 Lilsberg 1962 1968) The staining is progressive i e. the dye is bound to anions in the tissue until there are no more free negative groups available, after which the staining intensity will not increase. The bind ing is so stable that the staining is not in fluenced by alcohol or xylol during the dehy dration or mounting (Einarson 1951 Lilsberg 1962) The staining is not changed by storage for a long time or by exposure to light (Einar son 1934 Oram 1955 Kasten et al 1962, Sandritter et al 1963)

The pH in the gallocyanin-chromalum solu tion is 1 64 i e. far on the acid side of the iso-electric point of the proteins. At this pH the proteins will have positive charges and will therefore be unable to bind the positively charged dye lake. The only possible explana tion of the binding of the stain is linkage of the positive lake cation to negative groups in the strong mineral acids, i. e the phosphoric acid in the nucleic acids (Lilsberg 1962)

The very weak unspecific co-staining of the tissue which can be seen is probably due to adsorption of the basic $(CH_3)_2N$ groups in the dye, the lake sulphate (Einarson 1951) At the low pH the co-staining is without significance but it increases with higher pH

The strong, deep-blue colour with gallocyanin-chromalum is specific for nucleic acids. The specificity is confirmed by the good agreement which is found between measurements of the nucleic acid content by means of absorption of ultraviolet light and the gallocyanin-chromalum staining (Lagerstedt 1949 Sandritter 1955 Sandritter et al. 1957 Kiefer et al. 1967).

The specificity has also been confirmed by ribonuclease (RNase) experiments. After RNase treatment of nervous tissue it was shown that it was not possible to stain the Nissl substance with gallocyanin-chromalum (Sandritter 1955 Bech 1957 Sandritter et al. 1957 Schümmelfeder et al. 1958, Pakkenberg 1958, Lenberg 1962 Goncalves & Haddad (in press) Haddad 1968 a)

Electron-microscopic studies have further confirmed the specificity of gallocyanin-chromalum for nucleic acids in yeast cells (Mundkur 1961 1964)

According to the staining theory gallocyanin-chromalum is linked to the strongly acid phosphate groups of the nucleic acids. The proteins are not dissociated, as the only groups which can have a negative charge at this low pH (pH 1 64) are the strong mineral acids. In agreement with this, it can be expected that linkage to other strongly acid groups in the tissues may occur and it has in fact been shown that acid mucopolysaccharides will stain (Sandritter 1955 Schümmelfeder et al 1958 Lilsberg 196.., Haddad 1968 a, b) However it is a characteristic feature that the staining cannot be removed by treatment with RNase and that it is unmistakably metachromatic in the red area, which at the low pH indicates mucin sulphate (Curran 1964) Furthermore mucin is PAS-positive and can be eliminated as a source of error by its localization and the morphology of the tissue (e. g. in the goblet cells of the bronchial epithelium)

With the above-mentioned reservation, the staining of the nucleic acids with gallocyanin-chromalum is specific, and the blue orthochromatic staining of the nucleic acids is, without reservation, specific for them.

The condition for using a dye for quantitative histochemical determinations is that Beer Lambert's law applies to it, i. e. that the extinction is proportional to the concentration and the thickness of the absorbing substance. That the binding of gallocyanin-chromalum to the nucleic acids is progressive and quantitative was emphasized by Einarson (1947 1951).

Lambert's law which says that the extinction is proportional to the thickness, is valid for nucleic acid-bound gallocyanin-chromalum both in vitro and in histological sections (Diefenbach & Sandritter 1954 Sandritter et al. 1954 Pakkenberg 1958 Sandritter Kiefer & Rick 1963 1966).

Beer's law (the extinction is proportional to the concentration) has been shown for gallocyanin-chromalum in vitro (Diefenbach & Sandritter 1954 Sandritter et al. 1954 Sandritter et al. 1963) In histological sections, Beer's law can be proved only indirectly (Kasten 1958) by the absorption curve being the same for tissue-bound gallocyanin-chromalum in nuclei with different extinctions. Gallocyanin-chromalum also fulfils this requirement (Diefenbach & Sandritter 1954 Sandritter et al. 1963) That gallocyanin-chromalum is linked stoichelometrically to nucleic acids in tissues was shown by Jobst & Sandritter (1961 1964) and by Kiefer et al. (1967)

It thus appears that Beer-Lambert's law is valid for gallocyanin-chromalum linked to nucleic acids, both in vitro and tissue-bound in histological sections.

Ribonuclease

RNase was introduced in histology by Brachet (1940). This enzyme is widely used in tissue

the specificity of various stains for RNA As already mentioned it has been used in many investigations for the demonstration of the specificity of gallocyanin-chromalum In addition RNase is employed for the specific demonstration of RNA (Brachet & Shaver 1948) and in semi-quantitative determinations of DNA in cell nuclei by photometric absorption measurements after the removal of RNA

The enzyme is a nuclease or a nucleode polymerase (Pearse 1961) It splits specifically the bond between 3 pyrimidine nucleotide and the adjoining 5 hydroxyl group in the adjacent purine or pyrimidine nucleotide In this way 3 pyrimidine nucleotides and oligonucleotides of different degrees of polymerization are formed (Schmidt 1955 Scholtissek 1966)

The effect of RNase depends on the conditions under which it acts (the solvent, temperature, pH concentration and time) and first and foremost, on the pre treatment, i. e the fixation of the tissue

The techniques described for the use of RNase vary widely The enzyme is thermostable (Swift 1955) and has been employed by various investigators at temperatures ranging from 20 to 60° most frequently about 37° Depending on the temperature the concentration of the enzyme and the time required vary The pH optimum is within the range from 7 4 to 7 6 (Kaufmann et al. 1951 Jonsson & Lagerstedt 1957 Josefsson & Lagerstedt 1962) RNase is used dissolved in distilled water or in various buffers (Stowell & Zerzoli 1947 Sandritter et al 1957 Goncalves & Haddad 1966) The presence of electrolytes is an advantage in the use of RNase, as a rapid and complete breakdown of RNA will then occur (Greenstein et al. 1947 Markham et al. 1952 Edström 1953)

A notable property of RNA is its solubility During preparation of histological sections a certain loss of RNA from the cells will occur Some fractions are more readily soluble than others The use of fixatives reduces unwanted loss of RNA but some soluble nucleotides are apparently removed (Stowell & Zerzoli 1947 Swift 1966 a) s-RNA is probably removed by most aqueous fixatives, including formalin. Most fixatives preserve protein bound RNA, but strongly acid fixatives can, after fixation for a long time, eliminate some RNA by hydrolysis (Swift 1966 a)

By ultraviolet absorption measurements, Davies (1954) observed loss of nucleic acids both from formalin- and Carnoy fixed nuclei, as well as from formalin-fixed cytoplasm. However a certain loss which may be due to factors other than the fixative cannot be excluded, and no regard was paid to the redistribution after the fixation By chemical determination of RNA in the guinea-pig liver a loss of 20 % was found after fixation in Carnoy s solution for 2 hours (Harbers & Neumann 1955)

In contrast to these studies, Hartleib et al. (1956) did not observe any loss of nucleic acid phosphate by chemical determination after formalin fixation or fixation in Carnoy s solution, nor after further treatment of the tissue. Formalin and most acid fixatives do not cause a significant loss of nucleic acids from the cell (Kurnick 1955)

By RNase treatment of and ultraviolet absorption measurements on formalin-fixed pancreatic tissue, Lagerstedt (1956 1957) showed that the amount of liberated nucleotides was only 60 % of that liberated after fixation in Carnoy's solution. The explanation might be that not all formalin-fixed RNA could be removed by means of RNase This may thus apply to Schiff's bases (Fraenkel-Conrat 1954) which are formed by a reaction between amino groups in the RNA molecule and formalin As formalin inhibits the RNase activity considerably more than Carnoy s solution (Jonsson & Lagerstedt 1957 1959) a contributory cause might be that not all formalin was washed out of the tissue and thus inhibited the RNase activity (Swift 1966 a)

Finally it is possible that formalin extracts some RNA during the fixation. Lagerstedt (1957) found that this assumption was supported by the fact that extraction with perchloric acid liberated only about 60 % of th

content of nucleotides from the formalin-fixed tissue, as compared with Carnoy-fixed tissue.

It is likely that not all RNA is decomposed with the same ease by RNase. Cytoplasmic RNA will thus often be removed more easily and before RNA in the nucleolus and in the chromosomes (Swift 1966 a, Bonner et al. 1968). Sandritter et al (1963) showed that a weak staining of the Nissl substance remained in formalin-fixed nervous tissue after treatment with RNase. Similar observations were made by Amano (196?) Haddad (1968 a) and Goncalves & Haddad (in press) whereas Pakkenberg (1958 1959) showed that all RNA in the Nissl substance was removed by treatment with RNase of formalin-alcohol-fixed brain tissue. The significance of thorough rinsing of formalin-fixed tissue was emphasized by Pakkenberg (1962 a).

RNA in the Nissl substance is removed completely by RNase after fixation in Carnoy's solution (Sandritter 1955 Bech 1957 Lilsberg 196., Haddad 1968 a, Goncalves & Haddad (in press)) However the decomposition of RNA is usually complete after formalin fixation (Stowell & Zerzoli 1947 Lagerstedt 1956, 1957 Sandritter et al. 1957 Swift 1966 a) This has also been shown electron-microscopically by Mundkur (1961 1964)

Jonsson & Lagerstedt (1958) found that by flattening on water of paraffin sections fixed in Carnoy's solution a considerable loss of nucleic acids occurred in the water bath, while no loss was observed in formalin-fixed tissue. Other investigators, too, have found a varying loss of cytoplasmic RNA in Carnoy-fixed tissue in various buffers or in distilled water without RNase (Brachet 1953) while only a very slight loss, or none at all, occurred in formalin-fixed tissue (Stowell & Zerzoli 1947 Lagerstedt 1956, Amano 196., Goncalves & Haddad 1966)

It is generally assumed that formalin is a suitable fixative for RNA prior to RNase treatment (Kurnick 1955 Pearse 1961 Swift 1966 a)

Photometry

The theoretical and practical basis for microphotometry was elaborated by Caspersson (1936) with the development of ultraviolet microphotometry Photometry in visible light on stained sections is preferred by many investigators on account of a less costly and less complicated equipment which in many respects is fully equal to photometry in ultraviolet light in practical histochemistry (Pollister 1952 b Swift 1955)

A condition for photometric measurements is that Beer Lambert's law applies, i.e., that the extinction is proportional to the concentration and thickness of the absorbing substance, and in photometry in visible light, that the dye combines stoichiometrically with the substance to be measured. As already mentioned, these conditions are both fulfilled for gallocyanin-chromalum.

The principle of microphotometry is simple. There are certain sources of error both in the apparatus and in the object, but usually errors in the apparatus does not play any significant role (Sandritter 1966).

It is an advantage to use monochromatic light as the absorption can then be measured at well-defined wave lengths, and it is possible by varying the wave length, to measure the absorption in areas where the extinction is within suitable ranges (Sandritter et al. 1959)

A great numeric aperture of the objective should preferably be used, so that the greater part of the transmitted light from the object is included and the unspecific loss of light is reduced (Swift 1953 Sandritter 1966) On account of the thickness of the histological sections it is also a distinct advantage to use a great numeric aperture of the objective.

The numeric aperture of the condensor is not of as great significance as was previously assumed (Sandritter 1966). The condensor aperture should be smaller than that of the objective. Davies & Walker (1953) and Sandritter et al. (1959) recommended a condensor aperture of $^1/_3$–$^2/_3$ of the value of that of the

the specificity of various stains for RNA As already mentioned, it has been used in many investigations for the demonstration of the specificity of gallocyanin-chromalum. In addition, RNase is employed for the specific demonstration of RNA (Brachet & Shaver 1948) and in semi-quantitative determinations of DNA in cell nuclei by photometric absorption measurements after the removal of RNA

The enzyme is a nuclease or a nucleode polymerase (Pearse 1961) It splits specifically the bond between 3 pyrimidine nucleotide and the adjoining 5 hydroxyl group in the adjacent purine or pyrimidine nucleotide. In this way 3 pyrimidine nucleotides and oligonucleotides of different degrees of polymerization are formed (Schmidt 1955 Scholtissek 1966)

The effect of RNase depends on the conditions under which it acts (the solvent, temperature, pH concentration and time) and first and foremost, on the pre-treatment i. e. the fixation of the tissue

The techniques described for the use of RNase vary widely The enzyme is thermostable (Swift 1955) and has been employed by various investigators at temperatures ranging from 20 to 60° most frequently about 37° Depending on the temperature the concentration of the enzyme and the time required vary The pH optimum is within the range from 7 4 to 7 6 (Kaufmann et al 1951 Jonsson & Lagerstedt 1957 Josefsson & Lagerstedt 1962) RNase is used dissolved in distilled water or in various buffers (Stowell & Zerzoli 1947 Sandritter et al. 1957 Goncalves & Haddad 1966) The presence of electrolytes is an advantage in the use of RNase, as a rapid and complete breakdown of RNA will then occur (Greenstein et al 1947 Markham et al. 1952, Edstrom 1953)

A notable property of RNA is its solubility During preparation of histological sections a certain loss of RNA from the cells will occur Some fractions are more readily soluble than others. The use of fixatives reduces unwanted loss of RNA but some soluble nucleotides are apparently removed (Stowell & Zerzoli 1947 Swift 1966 a) s-RNA is probably removed by most aqueous fixatives, including formalin. Most fixatives preserve protein bound RNA but strongly acid fixatives can, after fixation for a long time, eliminate some RNA by hydrolysis (Swift 1966 a)

By ultraviolet absorption measurements, Davies (1954) observed loss of nucleic acids both from formalin- and Carnoy fixed nuclei, as well as from formalin-fixed cytoplasm. However a certain loss which may be due to factors other than the fixative cannot be excluded and no regard was paid to the redistribution after the fixation. By chemical determination of RNA in the guinea pig liver a loss of 20 % was found after fixation in Carnoy s solution for 2 hours (Harbers & Neumann 1955)

In contrast to these studies, Hartleib et al. (1956) did not observe any loss of nucleic acid phosphate by chemical determination after formalin fixation or fixation in Carnoy s solution, nor after further treatment of the tissue. Formalin and most acid fixatives do not cause a significant loss of nucleic acids from the cell (Kurnick 1955)

By RNase treatment of and ultraviolet absorption measurements on formalin-fixed pancreatic tissue, Lagerstedt (1956 1957) showed that the amount of liberated nucleotides was only 60 % of that liberated after fixation in Carnoy s solution The explanation might be that not all formalin fixed RNA could be removed by means of RNase This may thus apply to Schiff's bases (Fraenkel-Conrat 1954) which are formed by a reaction between amino groups in the RNA molecule and formalin. As formalin inhibits the RNase activity considerably more than Carnoy s solution (Jonsson & Lagerstedt 1957 1959) a contributory cause might be that not all formalin was washed out of the tissue and thus inhibited the RNase activity (Swift 1966 a)

Finally it is possible that formalin extracts some RNA during the fixation. Lagerstedt (1957) found that this assumption was supported by the fact that extraction with perchloric acid liberated only about 60 % of the

content of nucleotides from the formalin-fixed tissue, as compared with Carnoy-fixed tissue.

It is likely that not all RNA is decomposed with the same ease by RNase. Cytoplasmic RNA will thus often be removed more easily and before RNA in the nucleolus and in the chromosomes (Swift 1966 a, Bonner et al. 1968). Sandritter et al. (1963) showed that a weak staining of the Nissl substance remained in formalin-fixed nervous tissue after treatment with RNase. Similar observations were made by Amano (1962), Haddad (1968 a) and Goncalves & Haddad (in press), whereas Pakkenberg (1958 1959) showed that all RNA in the Nissl substance was removed by treatment with RNase of formalin-alcohol-fixed brain tissue. The significance of thorough rinsing of formalin-fixed tissue was emphasized by Pakkenberg (1962 a)

RNA in the Nissl substance is removed completely by RNase after fixation in Carnoy's solution (Sandritter 1955 Bech 1957 Lilsberg 1962, Haddad 1968 a, Goncalves & Haddad (in press)) However the decomposition of RNA is usually complete after formalin fixation (Stowell & Zerzoli 1947 Lagerstedt 1956, 1957 Sandritter et al. 1957 Swift 1966 a) This has also been shown electron-microscopically by Mundkur (1961 1964)

Jonsson & Lagerstedt (1958) *found that by* flattening on water of paraffin sections fixed in Carnoy's solution a considerable loss of nucleic acids occurred in the water bath, while no loss was observed in formalin-fixed tissue. Other investigators, too, have found a varying loss of cytoplasmic RNA in Carnoy-fixed tissue in various buffers or in distilled water without RNase (Brachet 1953) while only a very slight loss, or none at all, occurred in formalin-fixed tissue (Stowell & Zerzoli 1947 Lagerstedt 1956 Amano 1962, Goncalves & Haddad 1966).

It is generally assumed that formalin is a suitable fixative for RNA prior to RNase treatment (Kurnick 1955 Pearse 1961 Swift 1966 a)

Photometry

The theoretical and practical basis for microphotometry was elaborated by Caspersson (1936) with the development of ultraviolet microphotometry Photometry in visible light on stained sections is preferred by many investigators on account of a less costly and less complicated equipment which in many respects is fully equal to photometry in ultraviolet light in practical histochemistry (Pollister 1952 b, Swift 1955)

A condition for photometric measurements is that Beer Lambert's law applies, i. e., that the extinction is proportional to the concentration and thickness of the absorbing substance, and in photometry in visible light, that the dye combines stoichiometrically with the substance to be measured. As already mentioned, these conditions are both fulfilled for gallocyanin-chromalum.

The principle of microphotometry is simple. There are certain sources of error both in the apparatus and in the object, but usually errors in the apparatus does not play any significant role (Sandritter 1966)

It is an advantage to use monochromatic light as the absorption can then be measured at well-defined wave lengths, and it is possible by varying the wave length, to measure the absorption in areas where the extinction is within suitable ranges (Sandritter et al. 1959)

A great numeric aperture of the objective should preferably be used, so that the greater part of the transmitted light from the object is included and the unspecific loss of light is reduced (Swift 1953 Sandritter 1966). On account of the thickness of the histological sections it is also a distinct advantage to use a great numeric aperture of the objective.

The numeric aperture of the condensor is not of as great significance as was previously assumed (Sandritter 1966) The condensor aperture should be smaller than that of the objective Davies & Walker (1953) and Sandritter et al. (1959) recommended a condensor aperture of $^1/_2$–$^1/_3$ of the value of that of the

the specificity of various stains for RNA As already mentioned, it has been used in many investigations for the demonstration of the specificity of gallocyanin-chromalum In addition, RNase is employed for the specific demonstration of RNA (Brachet & Shaver 1948) and in semi-quantitative determinations of DNA in cell nuclei by photometric absorption measurements after the removal of RNA

The enzyme is a nuclease or a nucleode polymerase (Pearse 1961) It splits specifically the bond between 3 pyrimidine nucleotide and the adjoining 5 hydroxyl group in the adjacent purine or pyrimidine nucleotide In this way 3 pyrimidine nucleotides and oligonucleotides of different degrees of polymerization are formed (Schmidt 1955 Scholtissek 1966)

The effect of RNase depends on the conditions under which it acts (the solvent, temperature, pH concentration and time) and first and foremost, on the pre treatment, i e the fixation of the tissue

The techniques described for the use of RNase vary widely The enzyme is thermostable (Swift 1955) and has been employed by various investigators at temperatures ranging from 20 to 60° most frequently about 37° Depending on the temperature the concentration of the enzyme and the time required vary The pH optimum is within the range from 7 4 to 7 6 (Kaufmann et al 1951 Jonsson & Lagerstedt 1957 Josefsson & Lagerstedt 1962) RNase is used dissolved in distilled water or in various buffers (Stowell & Zerzoli 1947 Sandritter et al 1957 *Goncalves & Haddad 1966)* The presence of electrolytes is an advantage in the use of RNase, as a rapid and complete *breakdown of* RNA *will then occur* (Greenstein et al 1947 Markham et al 1952 Edström 1953)

A *notable* property of RNA is its solubility During preparation of histological sections a certain loss of RNA from the cells will occur Some fractions are more readily soluble than others The use of fixatives reduces unwanted loss of RNA but some soluble nucleotides are *apparently* removed (Stowell & Zerzoli 1947 Swift 1966 a) s-RNA is probably removed by most aqueous fixatives, including formalin. Most fixatives preserve protein bound RNA, but strongly acid fixatives can, after fixation for a long time, eliminate some RNA by hydrolysis (Swift 1966 a)

By ultraviolet absorption measurements, Davies (1954) observed loss of nucleic acids both from formalin- and Carnoy fixed nuclei, as well as from formalin-fixed cytoplasm. However a certain loss which may be due to factors other than the fixative cannot be excluded and no regard was paid to the redistribution after the fixation. By chemical determination of RNA in the guinea-pig liver a loss of 20 % was found after fixation in Carnoy s solution for 2 hours (Harbers & Neumann 1955)

In contrast to these studies, Hartleib et al. (1956) did not observe any loss of nucleic acid phosphate by chemical determination after formalin fixation or fixation in Carnoy s solution, nor after further treatment of the tissue. Formalin and most acid fixatives do not cause a significant loss of nucleic acids from the cell (Kurnick 1955)

By RNase treatment of and ultraviolet absorption measurements on formalin fixed pancreatic tissue, Lagerstedt (1956 1957) showed *that the amount of liberated nucleotides was* only 60 % of that liberated after fixation in Carnoy s solution The explanation might be *that not all formalin fixed* RNA *could be removed* by means of RNase. This may thus apply to Schiff's bases (Fraenkel-Conrat 1954) which are *formed* by a reaction between amino groups in the RNA molecule and formalin As formalin inhibits the RNase activity considerably more than Carnoy s solution (Jonsson & Lagerstedt 1957 1959) a contributory cause might be that not all formalin was washed out of the tissue and thus inhibited the RNase activity (Swift 1966 a)

Finally it is possible that formalin extracts some RNA during the fixation Lagerstedt (1957) found that this assumption was supported by the fact that extraction with perchloric acid liberated only about 60 % of the

content of nucleotides from the formalin-fixed tissue, as compared with Carnoy-fixed tissue.

It is likely that not all RNA is decomposed with the same ease by RNase. Cytoplasmic RNA will thus often be removed more easily and *before RNA in the nucleolus* and in the chromosomes (Swift 1966 a, Bonner et al. 1968). Sandritter et al. (1963) showed that a weak staining of the Nissl substance remained in formalin-fixed nervous tissue after treatment with RNase. Similar observations were made by Amano (1962) Haddad (1968 a) and Goncalves & Haddad (in press), whereas Pakkenberg (1958, 1959) showed that all RNA in the Nissl substance was removed by treatment with RNase of formalin-alcohol-fixed brain tissue. The significance of thorough rinsing of formalin-fixed tissue was emphasized by Pakkenberg (1962 a).

RNA in the Nissl substance is removed completely by RNase after fixation *in Carnoy's* solution (Sandritter 1955 Bech 1957 Lilsberg 1962, Haddad 1968 a, Goncalves & Haddad (in press)). However the decomposition of RNA is usually complete after formalin fixation (Stowell & Zerzoli 1947 Lagerstedt 1956, 1957 Sandritter et al. 1957 Swift 1966 a) This has also been shown electron-microscopically by Mundkur (1961 1964)

Jonsson & Lagerstedt (1958) found that by flattening on water of paraffin sections fixed in Carnoy's solution a considerable loss of nucleic acids occurred in the water bath, while no loss was observed in formalin-fixed tissue. Other investigators, too, have found a varying loss of cytoplasmic RNA in Carnoy-fixed tissue in various buffers or in distilled water without RNase (Brachet 1953) while only a very slight loss, or none at all, occurred in formalin-fixed tissue (Stowell & Zerzoli 1947 Lagerstedt 1956, Amano 1962, Goncalves & Haddad 1966)

It is generally assumed that formalin is a suitable fixative for RNA prior to RNase treatment (Kurnick 1955 Pearse 1961 Swift 1966 a).

Photometry

The theoretical and practical basis for microphotometry was elaborated by Caspersson (1936) with the development of ultraviolet microphotometry Photometry in visible light on stained sections is preferred by many investigators on account of a less costly and less complicated equipment which in many respects is fully equal to photometry in ultraviolet light in practical histochemistry (Pollister 1952 b, Swift 1955)

A condition for photometric measurements is that Beer Lambert's law applies, i. e., that the extinction is proportional to the concentration and thickness of the absorbing substance, and in photometry in visible light, that the dye combines stoichelometrically with the substance to be measured. As already mentioned, these conditions are both fulfilled for gallocyanin-chromalum.

The principle of microphotometry is simple. There are certain sources of error both in the apparatus and in the object, but usually errors in the apparatus does not play any significant role (Sandritter 1966)

It is an advantage to use monochromatic light as the absorption can then be measured at well-defined wave lengths, and it is possible by varying the wave length, to measure the absorption in areas where the extinction is within suitable ranges (Sandritter et al. 1959)

A great numeric aperture of the objective should preferably be used, so that the greater part of the transmitted light from the object is included and the *unspecific loss of light is reduced* (Swift 1953 Sandritter 1966) On account of the thickness of the histological sections it is also a *distinct advantage* to use a great numeric aperture *of the objective*.

The numeric aperture of the condensor is not of as great significance as was previously assumed (Sandritter 1966) The condensor aperture *should* be smaller than that of the objective. Davies & Walker (1953) and Sandritter et al. (1959) recommended a condensor aperture of [illegible]

objective A too small numeric aperture of the condensor may cause an unspecific loss of light, while a too great numeric aperture causes an increase in scattered light in the measuring area (Swift 1953) However a great numeric aperture also has an opposite effect, as the extinction on account of the longer oblique path of the light will increase (King & Roe 1953) Generally a condensor aperture of the order of 0 3 is recommended (Swift 1953 Sandritter 1966) but Ris & Mirsky (1950) found only very small changes by varying the condensor aperture from 0 25 to 0 85

Flare light, the Schwarzschild-Villiger effect, is a source of error which increases when the condensor aperture is too great, and when the illuminated area is too large as compared with the measuring area. The error tends to give too low values of the extinction, and increases with increasing extinction of the substance studied (Davies & Walker 1953 Richards 1966) This source of error is of significance only at high extinctions (Swift & Rasch 1956 Leuchtenberger 1958 Müller 1965 Sandritter 1966)

It is of importance for the measuring accuracy that the extinctions are within the range from 0 3 to 0 7 as the photometer is most accurate in this range (Lison 1950 Glick et al 1951 Davies & Walker 1953) Lison (1950) calculated the effective error of extinction measurements at an instrumental error of 0 5 % he found that the error becomes great when the percentage of transmission is greater than 80 or less than 5 i e at extinctions below 0 1 or above 1.3

The possibilities of errors in the object are greater Errors may be due to scattering, the *distribution of the absorbing substance* and the dimensions of the object (cell dimensions, size of the measuring area, thickness of the section)

Light scattering is no major problem in photometry on fixed and stained material in visible light. The scattering is *greater at short wave* lengths, and is a greater problem in photometry in ultraviolet light (Swift & Rasch 1956, Bammer 1960 Sandritter 1966) If the illuminated area is too large, there will be more *scattered light in the area, and it is therefore* an advantage to use a small illuminated area for the measurements (King & Roe 1953 Swift & Rasch 1956 Sandritter Schiemer et al 1958, Sandritter et al. 1959 Pakkenberg 1960) The percentage error increases with higher extinctions of the absorbing substance, for which reason it will be an advantage to measure away from the absorption maximum at high extinctions (Swift 1953 Swift & Rasch 1956)

The importance of the distributional error *caused by a heterogeneous distribution of the* absorbing material was critically assessed on the basis of theoretical calculations by Glick et al (1951) The error was also calculated by Caspersson et al (1957) and by Leuchtenberger (1958)

The distributional error will be greater with a coarser distribution of the absorbing particles The error can be reduced by integrating numerous measurements of a small measuring area (scanning) or by the two-wave method *(Patau 1952 Ornstein 1952) The error can,* however be shown empirically to be only of slight importance (Swift 1953 Lodin et al 1965) By comparative measurements on small and larger areas it can be shown that the distributional error in larger areas is negligible (Swift 1953) By control with the two-wave method it has been shown that the distributional error is of minor importance (Swift & Rasch 1956 Sandritter et al 1959) Similar observations were made by Ris & Mirsky (1950) and Sandritter et al (1960) demonstrated that the distributional error in normal gallocyanin-chromalum-stained nuclei is of the order of 1 % In absorption measurements by the "plug method" in which a measuring area of $^1/_4$–$^3/_4$ of the nucleus diameter is used, no essential error is introduced (Swift 1953 Swift & Rasch 1956) It may be shown mathematically that the error depends on the size of the *plug. With a very small central plug* the error is completely eliminated When the plug comprises the whole nucleus, the error is $^1/_{12}$ When

the size of the plug is $^3/_4$ or $^4/_5$ of the area of the nucleus, the error is only $^1/_{45}$ (Roels 1965)

The fixative is important for the distribution of the absorbing particles. Some fixatives give a coarser clumping than others. The distribution of chromatin is thus more homogeneous after fixation in formalin than in Carnoy's solution (Swift 1950 Pollister et al. 1951 Nurnberger et al. 1952, Davies 1954) The homogeneous distribution of the chromatin after formalin fixation was also emphasized by Kurnick (1955) By comparing nuclei fixed in formalin and nuclei fixed in isopropyl alcohol and a mixture of methanol, formalin and glacial acetic acid, *Böhm (1968) found* that the nuclei fixed in formalin were smaller and darker in colour with a distribution of chromatin which could hardly be differentiated, than after fixation with the other agents. This gives rise to a *smaller* distributional error but, on the other hand, also to extinctions which are too high to be optimal for absorption measurements. The distributional error increases with increasing extinctions (Garcia 1962 b), but can be reduced by measuring away from the absorption maximum where the extinction is greatest (Leuchtenberger 1958)

A special type of distributional error may occur in crystalloid structures owing to dichroism, where the absorbing molecules are orientated so that the absorption is greater in one plane than in another (Swift & Rasch 1956) However in most biological materials it possibly does not occur in sufficient degree to disturb photometric measurements, especially not in photometry on fixed and stained material in visible light, whereas the problem is greater with absorption measurements in ultraviolet light (Swift 1953)

A relative measure of the absorbing substance in a nucleus in measurements *by the* "plug method" can be calculated as the product of the extinction and the area of the absorbing nucleus. Only when the nucleus is a perfectly regular sphere is the *formula* absolutely correct. In biological materials, however practically no nuclei are of this regular shape, but more or less ellipsoid (Palkovits & Fischer 1968) If the asymmetry is not too great, the content of a substance as expressed by the area multiplied by the extinction may nevertheless be used in relative measurements in practical histochemistry (Ris & Mirsky 1950, Swift 1950, Sandritter et al. 1959 Müller 1960 Lison 1960, Jobst & Sandritter 1961 Allen 1962 Sandritter et al. 1963)

The area of the nucleus can be determined by measuring the diameters of the nuclei by means of an eyepiece micrometer (Kracht & Spaethe 1955 Swift 1950 Swift & Rasch 1956, Leuchtenberger 1958, Bader et al. 1960 Allen 1962, Pakkenberg & Vrå-Jensen 1964 Sod Moriah et al. 1968 Sachs 1968, Jacobsen 1968), even though planimetry must be regarded as a more accurate, but also a more time consuming procedure. By measuring the size of nuclei with eyepiece *rings*, *Sandritter et al.* (1960) found an error of 4–6 % as compared with planimetric measurements. Grundmann et al. (1961 a) calculated the area on the basis of the diameters *of* the nuclei in preference to planimetry as only a slightly better accuracy was obtained by the latter method. The measuring error for fixed diameters was very slight with a *coefficient* of variation of 3 % while, with new adjustments, it was 6 % (Garcia 1962 b) When a certain amount of practice and experience has been acquired, it is possible to obtain a reasonable accuracy and reproducibility by means of eyepiece micrometers *(Leuchtenberger* 1958, Jacobsen 1968)

In measuring extinctions in nuclei *it is of* importance that there are no parts of other nuclei in the measuring field. This can be avoided by careful focusing and by the use of great magnification and an objective with great resolution. By careful focusing it must, as far as possible, be ensured that the nucleus to be *measured is not cut, but* this may be difficult to assess with certainty (Sandritter & Pilny 1966)

Slight variations in the thickness of the sections is only *of minor importance in the estima-*

objective A too small numeric aperture of the condensor may cause an unspecific loss of light, while a too great numeric aperture causes an increase in scattered light in the measuring area (Swift 1953) However a great numeric aperture also has an opposite effect, as the extinction on account of the longer oblique path of the light will increase (King & Roe 1953) Generally a condensor aperture of the order of 0 3 is recommended (Swift 1953 Sandritter 1966) but Ris & Mirsky (1950) found only very small changes by varying the condensor aperture from 0 25 to 0 85

Flare light, the Schwarzschild Villiger effect is a source of error which increases when the condensor aperture is too great, and when the illuminated area is too large as compared with the measuring area The error tends to give too low values of the extinction, and increases with increasing extinction of the substance studied (Davies & Walker 1953 Richards 1966) This source of error is of significance only at high extinctions (Swift & Rasch 1956 Leuchtenberger 1958 Müller 1965 Sandritter 1966)

It is of importance for the measuring accuracy that the extinctions are within the range from 0 3 to 0 7 as the photometer is most accurate in this range (Lison 1950 Glick et al 1951 Davies & Walker 1953) Lison (1950) calculated the effective error of extinction measurements at an instrumental error of 0 5 % he found that the error becomes great when the percentage of transmission is greater than 80 or less than 5 i e. at extinctions below 0 1 or above 1 3

The possibilities of errors in the object are greater Errors may be due to scattering, the distribution of the absorbing substance and the dimensions of the object (cell dimensions, size of the measuring area, thickness of the section)

Light scattering is no major problem in photometry on fixed and stained material in visible light The scattering is greater at short wave lengths, and is a greater problem in photometry in ultraviolet light (Swift & Rasch 1956 Bammer 1960 Sandritter 1966) If the illuminated area is too large there will be more scattered light in the area, and it is therefore an advantage to use a small illuminated area for the measurements (King & Roe 1953 Swift & Rasch 1956 Sandritter Schiemer et al 1958 Sandritter et al 1959 Pakkenberg 1960) The percentage error increases with higher extinctions of the absorbing substance, for which reason it will be an advantage to measure away from the absorption maximum at high extinctions (Swift 1953 Swift & Rasch 1956)

The importance of the distributional error caused by a heterogeneous distribution of the absorbing material was critically assessed on the basis of theoretical calculations by Glick et al (1951) The error was also calculated by Caspersson et al (1957) and by Leuchtenberger (1958)

The distributional error will be greater with a coarser distribution of the absorbing particles The error can be reduced by integrating numerous measurements of a small measuring area (scanning) or by the two-wave method (Patau 1952 Ornstein 1952) The error can, however be shown empirically to be only of slight importance (Swift 1953 Lodin et al 1965) By comparative measurements on small and larger areas it can be shown that the distributional error in larger areas is negligible (Swift 1953) By control with the two-wave method it has been shown that the distributional error is of minor importance (Swift & Rasch 1956 Sandritter et al 1959) Similar observations were made by Ris & Mirsky (1950) and Sandritter et al (1960) demonstrated that the distributional error in normal gallocyanin-chromalum stained nuclei is of the order of 1 % In absorption measurements by the "plug-method in which a measuring area of 1/4–3/4 of the nucleus diameter is used, no essential error is introduced (Swift 1953 Swift & Rasch 1956) It may be shown mathematically that the error depends on the size of the plug. With a very small central plug the error is completely eliminated When the plug comprises the whole nucleus, the error is 1/12 When

MATERIAL AND METHODS

The material studied consisted of bronchial biopsy specimens from the Department of Oto-laryngology the University Hospital, Arhus. The specimens composing the material of mor phologically normal mucosae were secured during the period from October 1966 to June 1967 The patients were referred for broncho-scopy and possibly biopsy on suspicion of a pathological condition of the bronchial system. All biopsy specimens were taken under the same conditions, during the morning when the patients had been fasting from the evening before, and all patients were in general anaesthesia. The specimens were taken from the carina of the middle-lobe bronchus on the right side or in a few cases where this was not possible, from the carina between the upper and lower-lobe bronchus on the left side. All biopsies were performed by the same operator The specimen was removed from the forceps in physiological saline and immediately placed in 4 % formalin water neutralized by pulverized calcium carbonate. The advantage of using these small fragments of tissue is that imme diate fixation is obtained in the formalin, which has a high power of penetration and preserves the morphology of the epithelium (Wolman 1955 Gersh 1959 Swift 1966 a)

The specimens were fixed for 24 hours and then rinsed in tap water for another 24 hours. On the basis of experiments with human biopsy specimens the suitable time for the further treatment of the tissue was found to be 30 minutes 70 % alcohol (3 changes) 30 minutes 96 % alcohol (3 changes) 30 minutes 99 % alcohol (3 changes) After this the spe-cimens were placed in toluol until they became clear i.e for a couple of hours. They were then embedded in paraffin, 3 × 10 minutes at the melting point of the paraffin. The block was cut by a Leitz sledge microtome with an adjustment of the thickness of sections at 7 µm. The sections were flattened on water at 40 degrees in the shortest possible time, placed on a slide and deparaffinized in xylol, rehydrated in alcohol, rinsed in distilled water and stained with gallocyanin-chromalum for 48 hours.

The gallocyanin-chromalum solution is pre-pared as follows (Einarson 1951)· 10 g chrom alum is dissolved in 200 ml distilled water The solution is brought to the boil just before the boiling point is reached 0.3 g gallocyanin is added ("Chroma gallocyanin, D Grübler & Co., Stuttgart) The mixture is boiled for 5 minutes, and after cooling to room tempera-ture the solution is filtered, and distilled water is added through the filter until a volume of 200 ml is reached again. The dye solution was used to up 14 days after preparation.

After staining in a dark place for 48 hours the sections were rinsed 4 times in distilled water and after treatment with alcohol and xylol they were mounted in D P X. mountant (Kirk, Patrick & Lendrum, Edward Gurr Ltd., London) which has a refractive index of 1.515 The enzyme-treated sections were treated with RNase in a concentration of 1 mg per ml of Sorensen s phosphate buffer at pH 7 6 for two hours at 37 C (Ribonuclease-A Sigma, St. Louis, Missouri, U S. A.) The sections were then mounted on slides (Gold-Seal microslides, Clay Adams Inc., New York) of a thickness of 1.0 mm. The thickness of the cover glasses was 0 13 mm.

From each biopsy specimen, some sections were stained with haematoxylin-eosin for sur vey microscopy and with PAS. The thickness

tion and comparison of relative-quantitative determinations of the absorption by the cell *nuclei* All particles in the light conus participate in the light absorption, but to different degrees, so that the importance is inversely *related to the distance of the particle from the* plane of focus (Einarson 1960) This was shown experimentally by Jacobsen (1968) who did not find variations in the extinction of epithelial nuclei of the prostate when the thickness of the sections varied from 2 to 13 µm.

It is nevertheless of importance in nearly homogeneous nuclei that the cutting of the embedded tissue is as accurate as possible, so that the variations in thickness are within acceptable limits. The optical system should have so great a vertical resolving power that the depth of focus is smaller than the smallest variant in thickness of the tissue. This requires a great numeric aperture and a great total magnification (Einarson 1960) In addition, a sufficiently large number of measurements is necessary so that the thickness of the sections can be regarded as a statistical variable, the fluctuations of which are levelled out by the mean.

By measurements on the cytoplasm in gallocyanin-chromalum-stained tissue it has been shown (Pakkenberg 1958 Sandritter et al 1963 Jacobsen 1968) that Lambert's law is valid, i. e. that the extinction is proportional to the thickness of the section In studies of the concentration of RNA in the *cytoplasm* the thickness will then be a more significant factor

With the same adjustment of the microtome there is an appreciable variation in the thickness from section to section. Hallén (1962) found a variation of coefficient (standard deviation/mean × 100 %) of 28 % between different sections Pakkenberg (1958) found a variation of ± 50 % between different sections, and similar observations were reported by Holtet (1962)

Even in the same section there is some variation from area to area (Jacobsen 1968) even though it is considerably smaller than that between different sections. Hallén (1962) found a variation in measurements on the same section with a coefficient of variation of 6 % but his measurements were performed under optimal and far more accurate conditions than are normally used in the preparation of histological sections

The accuracy of the individual measurement by focusing is great. Brattgård (1954) found a coefficient of variation of 3 2 % while Lange & Engström (1954) found a coefficient of variation of about 10 % in thickness measurements on 5 µm sections, with a greater accuracy for thicker sections. Pakkenberg (1958) also reported that the focusing method yielded a great accuracy (± 0 06 µm) and similar observations were made by Hallén (1962): a coefficient of variation below 2 %

The variations between different sections is thus several times greater than those within the same section (Hallén 1962)

A large number of methods for the determination of the thickness of sections have been devised (Weissbach 1960) The earliest and most commonly used method is to focus on the upper and lower planes of the section recording the movements of the objective on a scale *(Hallén 1956) This method is* based on the investigations and calculations of focusing and vertical *resolving power performed by Abbé* and Berek (1927)

In measuring the thickness of a section it is of importance to use a great vertical power of resolution, which requires a great numeric aperture of the objective and a great total magnification (Berek 1927)

A mechanical method for measuring the thickness of the sections was elaborated by *Glimstedt & Håkansson (1951) who used a* microcator However this method involves a certain risk of mechanical deformation of the tissue even at the low pressure used in the measurements. The microcator was utilized for the registration of the small movements of the objective in determinations of the thickness of sections by Hallén (1956) Holtet (1962) and Jacobsen (1968)

MATERIAL AND METHODS

The material studied consisted of bronchial biopsy specimens from the Department of Oto-laryngology the University Hospital, Arhus. The specimens composing the material of mor phologically normal mucosae were secured during the period from October 1966 to June 1967 The patients were referred for broncho-scopy and possibly biopsy on suspicion of a pathological condition of the bronchial system. All biopsy specimens were taken under the same conditions, during the morning when the patients had been fasting from the evening before, and all patients were in general anaesthesia. The specimens were taken from the carina of the middle-lobe bronchus on the right side or in a few cases where this was not possible, from the carina between the upper and lower-lobe bronchus on the left side. All biopsies were performed by the same operator The specimen was removed from the forceps in physiological saline and immediately placed in 4 % formalin water neutralized by pulverized calcium carbonate. The advantage of using these small fragments of tissue is that imme diate fixation is obtained in the formalin, which has a high power of penetration and preserves the morphology of the epithelium (Wolman 1955 Gersh 1959 Swift 1966 a).

The specimens were fixed for 24 hours and then rinsed in tap water for another 24 hours. On the basis of experiments with human biopsy specimens the suitable time for the further treatment of the tissue was found to be: 30 minutes 70 % alcohol (3 changes) 30 minutes 96 % alcohol (3 changes) 30 minutes 99 % alcohol (3 changes) After this the spe cimens were placed in toluol until they became clear i.e. for a couple of hours. They were then embedded in paraffin, 3 × 10 minutes at the melting point of the paraffin. The block was cut by a Leitz sledge microtome with an adjustment of the thickness of sections at 7 µm. The sections were flattened on water at 40 degrees in the shortest possible time, placed on a slide and deparaffinized in xylol, rehydrated in alcohol, rinsed in distilled water and stained with gallocyanin-chromalum for 48 hours.

The gallocyanin-chromalum solution is pre pared as follows (Einarson 1951)· 10 g chrom alum is dissolved in 200 ml distilled water The solution is brought to the boil Just before the boiling point is reached 0.3 g gallocyanin is added ("Chroma gallocyanin, D Grübler & Co., Stuttgart). The mixture is boiled for 5 minutes, and after cooling to room tempera-ture the solution is filtered, and distilled water is added through the filter until a volume of 200 ml is reached again. The dye solution was used to up 14 days after preparation.

After staining in a dark place for 48 hours the sections were rinsed 4 times in distilled water and after treatment with alcohol and xylol they were mounted in D P X. mountant (Kirk, Patrick & Lendrum, Edward Gurr Ltd., London) which has a refractive index of 1.515 The enzyme-treated sections were treated with RNase in a concentration of 1 mg per ml of Sørensen s phosphate buffer at pH 7 6 for two hours at 37° C (Ribonuclease A, Sigma, St. Louis Missouri, U S. A.) The sections were then mounted on slides (Gold-Seal microslides, Clay-Adams Inc., New York) of a thickness of 1.0 mm. The thickness of the cover glasses was 0.13 mm.

From each biopsy specimen, some sections were stained with haematoxylin-eosin for sur vey microscopy and with PAS. The thickness

of the sections was determined by the microcator technique used by Holtet (1962) and Jacobsen (1968) The thickness was measured in four different places in the bronchial epithelium, and sections of an average thickness between 6 and 8 μm were used for photometric measurements. As already mentioned, the thickness varies from place to place in the same section and particularly from section to section, and even the determination is subject to slight errors The determinations of the thickness were made to exclude major divergences The sledge microtome proved relatively stable, the thickness of the sections being in most cases within the range from 6 to 8 μm

Photometric Measurements

The photometric measurements were carried out by means of a Leitz cytophotometer (Einarson et al 1965) which is constructed on a principle described by Hansen & Einarson (1956) The photometric arrangement is based upon the Leitz Ortholux microscope fitted with a special condensor system The modification from normal microscopy consists in an attachment replacing the ordinary ocular section The measuring area is selected by a prism system placed in the image plane and arranged so that the light from the remaining field of view is relayed to a viewing eyepiece The image seen in this eyepiece shows the measuring field accurately outlined as a centrally placed black area. Measurements in the image plane may be performed by the use of an eyepiece micrometer The magnification is determined by the objective and the interchangeable image-forming lens of the photometric attachment.

The photo multiplier is connected to a variable stabilized power supply which also includes facilities for dark current compensation. The signal current from the multiplier tube (modified by dark current compensation) is measured on a light-spot galvanometer (Kipp & Zonen) The gradation on this instrument comprises two scales on which the percentage transmission and extinction may be read directly

The source of light is a low voltage microscope lamp, which is supplied from a stabilized power supply The light reaches the microscope through a Leitz monochromator which was checked at regular intervals by means of the spectral lines of a mercury lamp and proved to be very stable

The field of illumination may be selected by the field stop of the condensor system. The smallest field stop was used for all measurements. The lens system of the condensor was throughout the investigations a microscope objective × 25 with a numeric aperture of 0.50. The objective system of the microscope itself was in all measurements an oil immersion objective × 100 with a numeric aperture of 1.30

The interchangeable image forming lens of the photometric attachment was "Optics No. 3" for all the nuclear measurements, which in the sections corresponded to a measuring field of 2 5 μm in diameter while the illuminated area was 23 μm in diameter Leitz "Optics No 4" was used for the cytoplasmic measurements. This gives a measuring field of 1.5 μm in diameter

In nuclear measurements, the nucleic acid content may be calculated in arbitrary units (A U) as extinction multiplied by area. The cross sectional area of the spheric or ellipsoid nuclei was taken as $\pi d^2/4$ and $\pi d_1 d/4$ respectively The constant factor $\pi/4$ was omitted in all determinations The content of nucleic acids is thus stated as $d_1 d$ E, where d_1 and d designate the small and the large diameter and E the extinction

The diameters of the nuclei were as already mentioned, determined by a Leitz eyepiece micrometer for which the micrometer value with "Optics No 3" is 3 85 μm (i. e. 1 unit in the eyepiece micrometer corresponds to 3 85 μm) and with Optics No 4 2 35 μm

In small nuclei of normal epithelium and in certain tumours the extinction was measured in one place centrally in the nucleus. In larger tumour nuclei in which the distribution of the

chromatin may be more irregular the extinction is stated as the average of 3–5 determinations.

In the measurements of the thickness of sections by means of the microcator in connection with the Leitz Ortholux microscope, an oil-immersion object-objective × 100 with a numeric aperture of 1.30 and an eyepiece × 12, were used.

The nuclear measurements were performed at a wave length of 510 nanometres (nm) Both the gallocyanin-chromalum solution and gallocyanin-chromalum-stained nuclei have an absorption maximum at 570 nm. As the nuclei are of a homogeneous appearance with a very dark colour the extinction in the nuclei is high. In order to obtain extinction values within an appropriate range where the error of the photometer is relatively slight, the extinction of the nuclei was determined away from the absorption maximum at 570 nm. 510 nm was found to be appropriate as the extinction of the bronchial epithelial nuclei at this wave length is of a suitable magnitude.

The prerequisites for using bronchial biopsy specimens for photometric determinations were that a sufficient amount of tissue was available that the tissue was not contused in the area on which measurements were to be made and that it was possible to obtain sections of the tissue cut at right angles to the surface, or nearly so (Palkovits & Fischer 1968, page 167) Furthermore, it was required that desquamation of the superficial layer of the epithelium had not occurred, so that the morphology of the intact epithelium could be assessed The measurements on the normal bronchial mucosae were all made in the basal cell layer The nuclei are here more regular more homogeneous and more uniform in shape and size than in the more superficial nuclei. They are also smaller which results in fewer cut nuclei

Having ensured that there was no overlapping of the nuclei, and that the nucleus appeared intact in the section, the extinction was determined in the central plug, and the small and large diameters were read on the eyepiece micrometer No measurements were made on extremely elongated nuclei in which the large diameter was more than 1½ times the small diameter (Leuchtenberger 1958). The nucleic acid content was determined in 30 nuclei.

The cytoplasmic measurements were made at the absorption maximum of 570 nm. As the nuclei were often lying close to each other and the rim of cytoplasm was narrow the small measuring field with a diameter of 1.5 µm was used. The determinations in the normal mucosae were made on the cytoplasm in the basal cell layer which does not contain PAS-positive material. The basophilic substance was completely removed with RNase, which shows that it consists of cytoplasmic RNA. 50 measurements were made on each section with one or two determinations per basal cell nucleus. It is important to use careful focusing to ensure that there are no sectioned parts of nuclei in the area to be measured. In the metaplastic mucosae, 150 measurements were made on each section, viz. 50 measurements in the basal, 50 in the intermediate, and 50 in the superficial cell layer In the tumours, 150 cytoplasmic measurements were made, viz. 50 determinations in three different places in the tumour tissue.

Material

In a preceding investigation, the bronchial epithelium had been studied in human autopsy material. A characteristic feature was very extensive autolytic processes with desquamation of the superficial cell layers of the epithelium, so that only the basal cell layer was preserved. Accordingly it was not possible to assess the morphology of intact epithelium. Autopsy could not be made until 12 hours post mortem at the earliest. In an autopsy material examined 6 hours post mortem, Auerbach et al. (1956) found that denudation of the epithelium was a considerable disadvantage in the study of autopsy material, and that it prevented the

investigation in more than half the cases. Similar observations were made by Cunningham et al. (1959) The advantage of using biopsy material is thus that immediate fixation of small tissue fragments with preservation of the morphology becomes possible As compared with specimens removed at operation biopsy specimens offer the advantage that it is possible to obtain fragments of normal mucosae from patients who do not suffer from pulmonary or bronchial disease. The biopsy specimens of bronchogenic tumours were taken from the peripheral prominent part of the tumour i. e from parts in which relatively slight necrosis is present. As it was not possible to obtain sufficient fresh material of different bronchogenic tumours, old formalin fixed biopsy material from the Institute of Pathology was also used In all cases, the fresh biopsy material was fixed in formalin in order to obtain as uniform treatment of the tissue as possible.

All morphologically normal bronchial mucosae and about half of the metaplastic mucosae were fresh biopsy material. Of 75 biopsy specimens, 36 fulfilled the criteria for microphotometric determinations. The tumours were all obtained from the Institute of Pathology The adenomata and adenocarcinomata were from the period 1962–1968 while the squamous-cell carcinomata and the small celled anaplastic carcinomata and some of the metaplastic mucosae originated from the period 1962–1965 The material included 107 blocks, of which 57 could be used for microphotometric measurements. All sections were revised and assessed together with a pathologist.

Personal Investigations

The relative-quantitative photometric determinations of the nucleic acid content in the bronchial epithelium were carried out on gallocyanin-chromalum stained tissue The absorption curve for the gallocyanin-chromalum solution was determined in two layers of different thickness 0 3 mm and 1 0 mm The measurements were performed by means of a Zeiss spectrophotometer

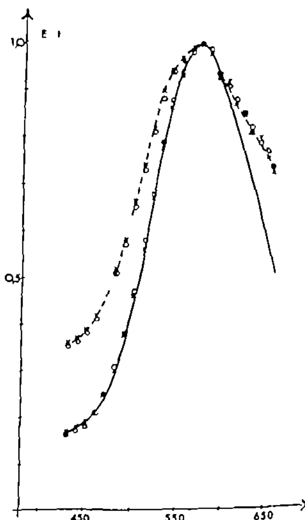

Fig. 1 —Absorption curves for gallocyanin-chromalum in solution (—O— and —×—) and tissue-bound (- - -O- - - and - - -×- - -)

The absorption curve for tissue bound gallocyanin-chromalum was determined on gallocyanin-chromalum-stained sections from two different bronchial specimens (Nos. 37 and 88) All values were related to each other by proportional calculation the absorption maximum fixed as the extinction value of 1 0 (fig. 1)

It is seen from the absorption curves for the gallocyanin-chromalum solution that the two curves for different thicknesses of the layers are identical which means that Lambert's law is valid for the gallocyanin-chromalum solution The absorption curves for the two nuclei are also identical (the two nuclei had a max

imal extinction of 0.90 and 0.94 respectively)

It is also seen that the tissue-bound gallocyanin-chromalum has an absorption curve occupying a higher level than that for the staining solution, especially in the short-wave area, but also, although to a lesser degree, in the long-wave area. The absorption maxima of gallocyanin-chromalum in solution and bound to nucleic acids are identical, i. e. there is no metachromasia.

The absorption curves for gallocyanin-chromalum in solution and in tissue have been determined by various investigators, who have reported similar results (Pakkenberg 1959 Sandritter et al. 1959) Both Sandritter et al. (1963) and Jacobsen (1968) found that the absorption curve for tissue-bound gallocyanin-chromalum in the short-wave area is somewhat higher than that for a gallocyanin-chromalum solution, while in the long-wave area it is only a little higher

Empirically it was found that the absorption in the nuclei of the bronchial epithelium at 510 nm, which was used for the nuclear measurements, was 73.5 % of that at the maximum of the extinction.

Errors of Measurements

Nuclear Measurements

The total nucleic acid content of the nuclei in the bronchial epithelium was calculated as the arithmetic mean of 30 non-enzyme-treated basal nuclei The values cluster around a mean with an average coefficient variation of 12.0 % (standard deviation/mean × 100). Figure 2 shows an example of the determination of the content of nucleic acids in the basal nuclei of a normal bronchial epithelium.

In order to check the accuracy measurements were performed on 30 nuclei in a normal bronchial epithelium. The measurements were repeated on the same section (No 28) at 4-hour intervals. The average content of nucleic acids was measured as 11.5 A. U 11.8 A. U 11.3 A. U and 11.3 A. U

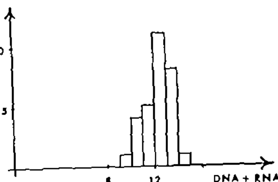

Fig. 2.—Nuclear nucleic acid content (section No. 22) Abscissa, nucleic acid content. Ordinate: number of nuclei. Mean 12.4 A.U standard deviation 1.1 A.U coefficient of variation 8.8 %

The maximal variation was 0.5 A. U., which in relation to the mean is a variation of 4.3 % i. e. good reproducibility exists within the individual section.

In a number of specimens the nucleic acid content in the nuclei was determined, both in different sections on the same slide and in sections mounted on different slides prepared at intervals of several months.

Table 1 *Nuclear nucleic acid content in different sections on the same slide*

Specimen No.	Section 1 A. U	Section 2 A. U	Variation A. U
28	11.5	11.5	0.0
37	12.4	12.6	0.2
41	14.3	14.0	0.3
44	13.6	14.3	0.7
55	11.2	12.7	1.5
57	14.1	13.2	0.9
61	13.0	13.4	0.4
62	12.9	12.6	0.3

In table 1 the average variation is 0.54 A. U which is an average variation of 4.1 % in relation to the mean.

From table 2 it appears that the average variation is 1.09 A. U., which is a variation of 8.7 % in relation to the mean.

In three cases, biopsy specimens of normal mucosae from different places of the bronchial tree were secured from the same patient (from

investigation in more than half the cases Similar observations were made by Cunningham et al (1959) The advantage of using biopsy material is thus that immediate fixation of small tissue fragments with preservation of the morphology becomes possible. As compared with specimens removed at operation, biopsy specimens offer the advantage that it is possible to obtain fragments of normal mucosae from patients who do not suffer from pulmonary or bronchial disease. The biopsy specimens of bronchogenic tumours were taken from the peripheral prominent part of the tumour i. e from parts in which relatively slight necrosis is present. As it was not possible to obtain sufficient fresh material of different bronchogenic tumours, old formalin-fixed biopsy material from the Institute of Pathology was also used In all cases, the fresh biopsy material was fixed in formalin in order to obtain as uniform treatment of the tissue as possible.

All morphologically normal bronchial mucosae and about half of the metaplastic mucosae were fresh biopsy material. Of 75 biopsy specimens, 36 fulfilled the criteria for microphotometric determinations. The tumours were all obtained from the Institute of Pathology The adenomata and adenocarcinomata were from the period 1962–1968 while the squamous-cell carcinomata and the small-celled anaplastic carcinomata and some of the metaplastic mucosae originated from the period 1962–1965 The material included 107 blocks, of which 57 could be used for microphotometric measurements. All sections were revised and assessed together with a pathologist.

Personal Investigations

The relative-quantitative photometric determinations of the nucleic acid content in the bronchial epithelium were carried out on gallocyanin-chromalum-stained tissue. The absorption curve for the gallocyanin-chromalum solution was determined in two layers of different thickness 0 3 mm and 1 0 mm The measurements were performed by means of a Zeiss spectrophotometer

The absorption curve for tissue-bound gallocyanin-chromalum was determined on gallocyanin-chromalum-stained sections from two different bronchial specimens (Nos. 37 and 88) All values were related to each other by proportional calculation, the absorption maximum fixed as the extinction value of 1 0 (fig 1)

It is seen from the absorption curves for the gallocyanin-chromalum solution that the two curves for different thicknesses of the layers are identical which means that Lambert's law is valid for the gallocyanin-chromalum solution The absorption curves for the two nuclei are also identical (the two nuclei had a max

urement on the individual section, which is probably due to variations in the thickness of the sections.

Table 5 *Cytoplasmic extinction in sections on different slides*

Specimen No	Section 1	Section 2	Variation
20	0.1827	0.1715	0.0112
22	0.1769	0.2006	0.0237
28	0.1603	0.1585	0.0018
31	0.1726	0.1739	0.0013
36	0.2046	0.1965	0.0081
59	0.1736	0.1485	0.0251

The average deviation is 0.0119 corresponding to a variation of the mean of 6.7 %. The average variation is of the same order as in table 4 and is probably due to variations in the thickness of the sections.

In three cases, biopsy specimens were secured from two different places of the bronchial tree in the same patient. The average values of the cytoplasmic extinction were as shown in table 6.

Table 6. *Average cytoplasmic extinction in specimens from two different places of the bronchial tree in the same patient*

Specimen No.	Section 1	Section 2	Variation
65–66	0.1777	0.1771	0.0006
67–68	0.1669	0.1552	0.0117
69–70	0.1[illegible]0	0.1461	0.0181

The average variation is 0.0101 corresponding to a variation in relation to the mean of 6.4 %.

While certain nuclear measurements in the fresh and older material can be directly compared (for example, the number of hyperdiploid and polyploid cell nuclei) because the values are relative, this cannot straight away be assumed as far as the cytoplasmic extinction measurements are concerned. In order to assess whether the deviating treatment of the older

NORMAL BRONCHIAL EPITHELIUM

Histological Structure

The epithelial elements of the bronchial tree are endodermally developed from a ventral diverticulum on the foregut (Hamilton et al. 1962).

The respiratory epithelium of the major bronchi is a pseudo-stratified columnar epithelium with kinocilia. The cell nuclei are arranged in two or three layers, but all cells extend down to the basement membrane. The basal cells do not reach the surface. Goblet cells are scattered in the epithelium. The epithelium rests on a basement membrane. Below this membrane is the lamina propria with loose connective tissue, which contains numerous small glands of a mixed mucous-serous type. In the lamina propria are scattered lymphocytes and accumulations of lymphatic tissue, either diffuse or as nodules (Messerklinger 1958, Bloom & Fawcett 1962).

The connective tissue contains hyalin cartilage in the trachea and large bronchi in the form of C-shaped rings. The deepest layers consist of smooth muscle cells and dense connective tissue (Bloom & Fawcett 1962)

Histologically different types of cells have been described in the respiratory epithelium. Chang (1957) mentioned four different types of cells. basal, intermediate ciliated and goblet cells.

The nuclei of the basal cell layer are mainly spherical in shape (Messerklinger 1958) They are regular and compact, and the nucleolus does not form any distinct structure (Rhodin & Dalhamn 1956). The cytoplasm is sparse around the basal cells and contains many granula presumed to be RNA (Rhodin & Dalhamn 1956)

The ciliated cells and the goblet cells are highly differentiated (Messerklinger 1958) In addition to these types, and superficial to the basal cells, there are various types of cells differing in morphology with or without secretory granules and PAS-positive material in the cytoplasm (Rhodin & Dalhamn 1956, Blenkinsopp 1967 Bindreiter et al 1968)

DNA Content of Normal Cell Nuclei

If the DNA content is determined microphotometrically in a number of nuclei in a histological section, a certain variation in the DNA values around a mean will be found with a coefficient of variation ranging from 7 to 20 % (Swift 1953 Alfert & Swift 1953 Jobst & Sandritter 1961 Garcia 1962 a, Alpen & Johnston 1966)

It is difficult to decide whether this variation is due to a real difference in the DNA content or merely to measuring errors. Small variations in the DNA content can hardly be revealed on account of photometric measuring errors (Vendrely & Vendrely 1956, Walker & Richards 1959)

Beatty (1954) considered the existence of inconstancy likely Some somatic cells with an abnormal number of chromosomes may be at the end of their life span and do not divide any more, but most of the cells with an abnormal chromosome number will have divided several times. Swift (1966 b) revealed variations in the DNA content which, at least in many tissues, exceeded that which could be explained solely on the basis of photometric errors. The variations can be taken as an expression partly of measuring errors and partly as real variations because of an irregular number of chromosomes

concentration of RNA is about 0 24 The dif ference between the lowest and highest values (0.22 and 0 25) is not even slightly significant ($P > 0\ 10$ P referring to the probability of ex ceeding the stated limit of the null hypothesis)

This analysis does not suggest that major changes in the cytoplasmic RNA concentration should occur as a consequence of the differ ences in the treatment of the tissue but rather that the variations observed can be ascribed to errors of measurement.

NORMAL BRONCHIAL EPITHELIUM

Histological Structure

The epithelial elements of the bronchial tree are endodermally developed from a ventral diverticulum on the foregut (Hamilton et al. 1962)

The respiratory epithelium of the major bronchi is a pseudo-stratified columnar epithelium with kinocilia. The cell nuclei are arranged in two or three layers, but all cells extend down to the basement membrane. The basal cells do not reach the surface. Goblet cells are scattered in the epithelium. The epithelium rests on a basement membrane. Below this membrane is the lamina propria with loose connective tissue, which contains numerous small glands of a mixed mucous-serous type In the lamina propria are scattered lymphocytes and accumulations of lymphatic tissue, either diffuse or as nodules (Messerklinger 1958 Bloom & Fawcett 1962)

The connective tissue contains hyalin cartilage, in the trachea and large bronchi in the form of C-shaped rings. The deepest layers consist of smooth muscle cells and dense connective tissue (Bloom & Fawcett 1962).

Histologically different types of cells have been described in the respiratory epithelium. Chang (1957) mentioned four different types of cells. basal, intermediate ciliated and goblet cells.

The nuclei of the basal cell layer are mainly spherical in shape (Messerklinger 1958). They are regular and compact, and the nucleolus does not form any distinct structure (Rhodin & Dalhamn 1956). The cytoplasm is sparse around the basal cells and contains many granula presumed to be RNA (Rhodin & Dalhamn 1956)

The ciliated cells and the goblet cells are highly differentiated (Messerklinger 1958) In addition to these types, and superficial to the basal cells, there are various types of cells differing in morphology with or without secretory granules and PAS-positive material in the cytoplasm (Rhodin & Dalhamn 1956, Blenkinsopp 1967 Bindreiter et al. 1968)

DNA Content of Normal Cell Nuclei

If the DNA content is determined microphotometrically in a number of nuclei in a histological section, a certain variation in the DNA values around a mean will be found with a coefficient of variation ranging from 7 to 20 % (Swift 1953 Alfert & Swift 1953 Jobst & Sandritter 1961 Garcia 1962 a, Alpen & Johnston 1966)

It is difficult to decide whether this variation is due to a real difference in the DNA content or merely to measuring errors. Small variations in the DNA content can hardly be revealed on account of photometric measuring errors (Vendrely & Vendrely 1956, Walker & Richards 1959)

Beatty (1954) considered the existence of inconstancy likely Some somatic cells with an abnormal number of chromosomes may be at the end of their life span and do not divide any more, but most of the cells with an abnormal chromosome number will have divided several times. Swift (1966 b) revealed variations in the DNA content which, at least in many tissues, exceeded that which could be explained solely on the basis of photometric errors. The variations can be taken as an expression partly of measuring errors and partly as real variations because of an irregular number of chromosomes

concentration of RNA is about 0.24 The dif ference between the lowest and highest values (0 22 and 0.25) is not even slightly significant ($P > 0\ 10$ P referring to the probability of ex ceeding the stated limit of the null hypothesis)

This analysis does not suggest that major changes in the cytoplasmic RNA concentration should occur as a consequence of the differ ences in the treatment of the tissue but rather that the variations observed can be ascribed to errors of measurement

(1952 a) failed to disclose any content of RNA in normal cell nuclei, whereas chemical determination on the same nuclei revealed a nuclear RNA content of about 7.5 %

Cytoplasmic RNA

The concentration of cytoplasmic RNA may to a certain extent be assessed visually in a histological section when a stoichelometrically reacting dye is used. However microphotometric methods are more accurate, as the concentration of cytoplasmic RNA can then be measured.

As emphasized by Davies & Walker (1953) and Sandritter Pilny et al. (1966) the concentration of RNA in the cytoplasm can be measured. It is much more difficult to determine the total content of RNA in the cytoplasm of the cell usually it is extremely difficult, if not impossible, to assess the cytoplasmic volume in histological sections.

Quantitative photometric determinations of cytoplasmic RNA have been made, both in visible light on gallocyanin-chromalum-stained material and by ultraviolet absorption measurements on unstained material.

Determinations of cytoplasmic RNA on gallocyanin-chromalum-stained tissue have been carried out both on nerve cells (Einarson 1951 Krogh & Einarson 1954 Einarson & Krogh 1955 Hansen & Einarson 1956 Bech 1957 Pakkenberg 1958 1959 1960 1962 b, 1963 Falbe Hansen & Pakkenberg 1963 Thomsen & Pakkenberg 1962, Pakkenberg & Thomsen 1964 Pakkenberg & Vrå-Jensen 1964 Einarson et al. 1965), and on secreting cells (Oram 1955 Weber 1958 Holtet 196).

Ultraviolet absorption measurements have been performed on cytoplasm in various tissues, primarily by the Swedish school (Caspersson 1936, Hydén 1943 Thorell 1947) but also by many other investigators (Lagerstedt 1949 Sandritter 1953 Attardi 1957 Seed 1966 a, 1966 b, Sundelin 1967)

Only a few studies of the cytoplasmic RNA concentration in respiratory epithelium are on record. Bertalanffy (1964) visually evaluated the content of cytoplasmic RNA in the alveolar cells of the rat and found that it was increased in chronic inflammatory conditions.

Sandritter Müller et al. (1958) studied the cytoplasmic absorption of sputum cells by ultraviolet microphotometry The cytoplasmic content of RNA in the ciliated cells was very low as compared with that in the squamous cells from the oral mucosa. They did not report on the cytoplasmic RNA content of the basal cells of the bronchial epithelium.

In a preliminary report, the present author presented investigations of the RNA concentration in bronchial epithelial cells from morphologically normal and from metaplastic human bronchial mucosae (Greisen 1968).

Personal Investigations

Normal human bronchial epithelium consists of a ciliated pseudo-stratified columnar epithelium with the nuclei arranged in two or three layers. In the lamina propria, lymphocytes are nearly always present either as single, scattered cells or as small nodules. Sero-mucous glands are often found in the lamina propria in biopsy specimens.

Nuclear Measurements

A total of 36 biopsy specimens of morphologically normal bronchial epithelium were studied. In each specimen, the nucleic acid content was determined in 30 basal nuclei of bronchial epithelium which had not been treated with RNase and the average content of nuclear nucleic acid was then calculated. (*In the calculations a small amount of cytoplasmic RNA was included, see page 41*)

In normal bronchial epithelium, there are a few nuclei with a content of DNA which is increased as compared with the DNA content in the majority of the nuclei. These cells, which are synthetizing DNA in preparation for mitosis, were excluded in the calculations (see page 48). The fact that some cells are synthetizing DNA involves the risk of a positive

(Alfert & Swift 1953) In two-wave photometry Patau & Swift (1953) found a DNA content which was in complete agreement with the hypothesis of the constancy of DNA and regarded variations as an expression of photometric measuring errors. The same conclusion was reached by Pollister et al (1951)

In normal tissue, cells with an abnormal chromosome number will always be present (Koller 1958 Sandberg et al. 1960 Visfeldt 1966) They seldom deviate from the normal diploid cells by more than one chromosome (Hauschka 1961) Aneuploid cells are found only with a low frequency (Hsu 1961)

Ford (1960) found that 0 4 % of the cells in reticular tissue in mice had an abnormal number of chromosomes. Similar conditions are presumably present in human tissue (Ford 1960 Hamerton 1961)

In a study of normal bone marrow Sandberg et al (1961) observed as much as 12 % aneuploid cells produced by mitotic irregularities in the haemopoiesis. In normally regenerating liver tissue, Stich (1963) revealed 0–3 % cells with mitotic irregularities and 0–2 1 % cells with aneuploid DNA values.

DNA Content of the Bronchial Epithelial Nuclei

Determinations of the DNA content in normal bronchial epithelium have been made in connection with studies of the DNA content in bronchogenic tumours (Stowell 1946 Boriani & Gandolfi 1961 Sandritter Seidel et al 1965) These investigations show that the DNA content in the bronchial nuclei, like that of other cells, centres around a mean and that the average value in normal epithelium is considerably lower than that observed in bronchogenic tumours.

By means of ultraviolet microphotometry Sandritter Müller et al (1958) studied the nucleic acid content in various types of cell nuclei from scrapings of the bronchial mucosa and found that the average values for the basal and ciliated cells were equal.

In mice exposed to tobacco smoke, Leuchtenberger et al (1958) determined the average content of DNA in the bronchial epithelial nuclei in order to find out whether histochemical alterations could be detected before morphological changes in the epithelium occurred No such alterations in the average content of DNA were disclosed, but a slightly larger volume of the nuclei and an increased content of nuclear protein were found in the tobacco-exposed animals as compared with a control group

RNA Content of the Cell Nuclei

In the chemical determination of the RNA content in isolated nuclei it is difficult to avoid contamination with cytoplasmic RNA while, on the other hand, loss of RNA may occur in the isolation of the nucleus (Swift 1953)

According to the reports, the RNA content in different organs and in cells in different states of function varies widely The ratio between DNA and nuclear RNA is reported to be from 0 6 1 to 40 1 most values, however being within the range from 10 1 to 20 1 i e the nuclear RNA content is 5–10 % of the total nucleic acid content of the cell nucleus.

Microphotometric determinations of the nuclear RNA content can be made on tissue specifically stained for nucleic acids or by means of ultraviolet microphotometry The RNA content is then calculated as the difference between the amounts of nuclear nucleic acid without and with RNase treatment.

By ultraviolet microphotometry Sandritter Jobst & Rakow (1965) found that thymic lymphocytes had a nuclear RNA content corresponding to 7 8 % of the total nucleic acid content of the cell nucleus. In liver-cell nuclei Sandritter et al (1957) using both ultraviolet photometry and microphotometry on gallocyanin-chromalum stained nuclei found a nuclear RNA content of 10 % of the total nucleic acid content of the cell nucleus. By ultraviolet microphotometry Leuchtenberger et al

specimens from perfectly healthy persons. However, the author succeeded in obtaining biopsy specimens from a group of patients with benign conditions unrelated to the bronchial system. These patients had no symptoms of bronchitis, bronchoscopy showed normal findings and the bronchial biopsy specimens secured consisted of morphologically normal bronchial mucosae. This group consisting of nine patients with mediastinal cysts or with uveitis without signs of sarcoidosis (Boeck) or other systemic disease served as controls.

Simple analysis of variance showed that $F < 1$ $(P > 0.50)$, i. e. there is no significant *difference between the groups. The variation* between the various groups is smaller than that within the individual groups.

Information was available of the smoking habits of eight of the nine subjects in the control group and of all the eight patients with bronchogenic carcinoma. In table 12, the use of tobacco is stated as + (less than 5 cigarettes daily), ++ (5–10 cigarettes daily), +++ (more than 20 cigarettes daily) and – (non-smokers).

It is seen that there is no difference in the amounts of the nuclear nucleic acid in the two groups.

In the cases where sufficient tissue was available, subsequent sections from each specimen were treated with RNase and the DNA content was measured on the basal cell nuclei. *In the control group and in the group of patients* with bronchogenic carcinoma and morphologically normal bronchial mucosae, it was *possible to measure the DNA content in seven* specimens from each group. Table 13 shows

Table 12 *Nuclear nucleic acid content in morphologically normal bronchial epithelium related to smoking habits. The range is shown in brackets*

the average total nuclear nucleic acid content in the two groups (nine subjects from the control group and eight patients from the group with bronchogenic carcinoma) and the DNA content in the same two groups (seven patients from each group).

From the table it appears that there is only a very slight difference in the amounts of nuclear nucleic acid in the two groups, and according to Student's t-test, the difference is far from being significant.

Cytoplasmic Measurements

The RNA concentration was measured around the basal nuclei in the 36 morphologically normal bronchial mucosae. For each section, the cytoplasmic extinction is stated as the average of 50 determinations.

The average extinctions in the sections ranged from 0.13 to 0.20, with an average of 0.17 for the entire series (fig. 10).

The average cytoplasmic extinction is related to age in table 14.

Simple analysis of variance showed that $F < 1$ $(P > 0.50)$ i.e. there is no significant difference between the groups. The variation

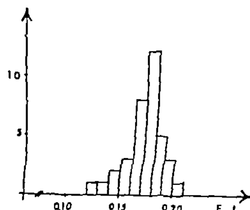

Fig. 10.—Distribution of the average cytoplasmic RNA concentration in morphologically normal bronchial epithelium.

the cytoplasmic RNA concentration in morphologically normal bronchial epithelium obtained from an uninvolved part of the bronchial tree in patients with bronchogenic carcinoma and from a control group.

RNase Treated Bronchial Epithelium

In the control group and in the group of patients with bronchogenic carcinoma, the nuclear nucleic acid content was measured in control sections treated with a phosphate buffer without RNase for 2 hours (pH 7.6, temperature 37 C).

Stowell & Zerzoli (1947) observed increased nuclear staining in buffer controls without RNase after fixation in Carnoy's solution, acetone and absolute alcohol. They presumed that the increased staining was due to adhesion to the nucleus of substances released from the cytoplasm. Toluidine blue and pyronine were used for the staining (pH not stated).

Jobst & Sandritter (1961) and Sandritter et al. (1963) found that treatment in a buffer for hours, with or without RNase gave rise to increased nuclear staining with gallocyanin-chromalum. They explained this phenomenon by release of phosphate groups now being available for the stain. Kaufmann et al. (1951) reported that fixed cells treated with RNase showed increased staining with acid dyes, but that the staining was eliminated by proteolytic enzymes, which proved that the increased staining was due to protein.

In a number of bronchial mucosae the nuclear nucleic acid content and the cytoplasmic RNA concentration were determined in the ordinary gallocyanin-chromalum-stained sections and in the above mentioned control sections (tables 17 and 18).

These studies show that as far as the bronchial epithelium is concerned, no alterations occur in the nucleic acid content in the nuclei or in the cytoplasm when the tissue is treated in a phosphate buffer for 2 hours (pH 7.6, temperature 37 C). The differences observed are very slight and far from being significant.

Table 17. *Nuclear nucleic acid content in morphologically normal non-enzyme treated bronchial epithelium.*

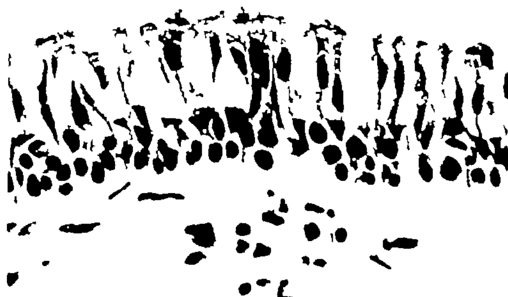

Fig. 9 —Normal bronchial epithelium (gallocyanin-chromalum. × 715).

between the age groups is smaller than that within the individual groups

As in the nuclear measurements, the cytoplasmic extinction is related to the diagnoses of the patients (table 15)

Simple analysis of variance showed that F < 1 (P > 0 50) i e there is no significant difference between the groups.

The cytoplasmic extinction is related to the use of tobacco in the control group and in the group of patients with bronchogenic carcinoma in table 16

It is seen that there is only a very slight difference between the groups, and that it is the reverse of what might have been expected The difference is far from being significant.

Conclusions

The nuclear nucleic acid content and the cytoplasmic RNA concentration in morphologically normal bronchial mucosae are distributed evenly around a mean of 12 6 A U and 0 17 respectively No evidence was revealed in favour of the assumption that the total nucleic acid content in the cell nuclei or the cytoplasmic RNA concentration should vary with the age diagnosis or tobacco consumption of the patients. No difference was demonstrated between the nuclear nucleic acid content and

the cytoplasmic RNA concentration in morphologically normal bronchial epithelium obtained from an uninvolved part of the bronchial tree in patients with bronchogenic carcinoma and from a control group

RNase-Treated Bronchial Epithelium

In the control group and in the group of patients with bronchogenic carcinoma, the nuclear nucleic acid content was measured in control sections treated with a phosphate buffer without RNase for 2 hours (pH 7 6 temperature 37 C)

Stowell & Zorzoli (1947) observed increased nuclear staining in buffer controls without RNase after fixation in Carnoy's solution, acetone and absolute alcohol. They presumed that the increased staining was due to adhesion to the nucleus of substances released from the cytoplasm. Toluidine blue and pyronine were used for the staining (pH not stated)

Jobst & Sandritter (1961) and Sandritter et al (1963) found that treatment in a buffer for 2 hours, with or without RNase, gave rise to increased nuclear staining with gallocyanin-chromalum They explained this phenomenon by release of phosphate groups now being available for the stain. Kaufmann et al. (1951) reported that fixed cells treated with RNase showed increased staining with acid dyes, but that the staining was eliminated by proteolytic enzymes, which proved that the increased staining was due to protein.

In a number of bronchial mucosae the nuclear nucleic acid content and the cytoplasmic RNA concentration were determined in the ordinary gallocyanin-chromalum-stained sections and in the above mentioned control sections (tables 17 and 18)

These studies show that as far as the bronchial epithelium is concerned, no alterations occur in the nucleic acid content in the nuclei or in the cytoplasm when the tissue is treated in a phosphate buffer for 2 hours (pH 7 6, temperature 37 C) The differences observed are very slight and far from being significant.

The cytoplasmic extinction was also measured in a number of sections around the basal nuclei, both without and with RNase treatment (table 19)

It is seen that the RNA content in the cytoplasm disappears completely after RNase treatment. This shows that the stained substance is RNA, and that gallocyanin-chrom alum specifically stains cytoplasmic RNA in the basal cells in the normal bronchial epithelium

Nuclear RNA Content

By measuring the total nuclear content of nucleic acid in the bronchial epithelium and the DNA content in the RNase treated sections, the RNA content of the nucleus may be calculated.

The studies were carried out on morphologically normal bronchial mucosae from the control group and the group of patients with bronchogenic carcinoma. For each patient, the content of nucleic acid is stated as the average of the total nucleic acid content in sections prepared in the ordinary way and in the control sections (tables 20 and 21)

The average nuclear RNA content was 0.71 A.U corresponding to 5.6 % RNA in the control group, and 0.79 A.U in the group with bronchogenic carcinoma corresponding to a nuclear RNA content of 6.3 %.

In these calculations, however, is included a factor conditional on the extinction in the cytoplasm surrounding the nucleus. The thickness of the nuclei in the bronchial epithelium (average 4.6 µm, see later) is not as great as that of the section (7 µm). On the assumption that the rim of cytoplasm is perfectly homogeneous, the cytoplasmic share of the extinction can be eliminated (Swift & Rasch 1956). If the basal nuclei are rotary ellipsoids (Abercrombie 1946, Grundmann et al. 1961 a) which sections cut parallel to the epithelial surface also suggest, the height of the cytoplasmic rim will be equal to the thickness of the section minus the short diameter of the nucleus. The average short and long diameters and the average extinction were calculated for each section. The cytoplasmic extinction and the unspecific cytoplasmic extinction after RNase treatment were measured. As the cytoplasmic extinction was measured at 570 nm, and the nuclear extinction at 510 nm, the cytoplasmic extinction must be corrected by the factor 0.735 (see page 27). Finally, the weak unspecific absorption of light in the over- and underlying rim of cytoplasm must be subtracted from the total nuclear extinction.

If E_t is the total extinction, E_k = the nuclear extinction, E_c = the cytoplasmic extinction, E_c = the corrected cytoplasmic extinction, d = the thickness of the section and a = the short diameter of the nucleus, then the following relation will be valid.

$$E_t = E_k + \frac{d - a}{d} \times E_c$$

which means that E_r constitutes

$$\frac{\frac{d-a}{d} \times E_r}{E_t} \times 100\,\%$$

of the total extinction (Swift & Rasch 1956)

That part of the total nuclear RNA content which is constituted by cytoplasmic RNA can now be calculated (tables 22 and 23)

It appears that the cytoplasmic RNA con centrations in the two patient groups constitute 5 0 % and 5 3 % of the total uncorrected nu clear RNA content. This was calculated to be 5 6 % and 6 3 % respectively of the total nu clear nucleic acid content.

If the cytoplasmic rim is perfectly homogeneous, the nuclear RNA content as a per centage of the total nucleic acid content of the nucleus will thus constitute.

5 6 % 5 0 % = 0 6 % in the control group and
6 3 % − 5 3 % = 1 0 % in the patient group with bronchogenic carcinoma.

The figures are too small to allow a statis tical comparison of the content in the two groups.

In the explanation of the low nuclear RNA content the following possibilities must be considered.

1 That actually only a small amount of RNA is present in the basal nuclei of the normal bronchial epithelium
2 That some nuclear RNA has been washed out of the nuclei during the preparation of the tissue.

It is likely that a certain loss of nuclear RNA occurs during the preparation of histological sections, primarily of s-RNA which constitutes about one third of the nuclear RNA content (Amano 1967 a 1967 b) (see page 14)

3 That some nuclear RNA is fixed so firmly by the formalin that it cannot be removed by RNase treatment

This is likely (see page 18)

4 That the average thickness of the section is not 7 μm

As mentioned on page 22 measurements of the thickness of the sections are subject to some uncertainty and in practice it is not possible to check the thickness of the sections in all areas where the cytoplasmic

extinction is measured. However the thickness of the sections was within the limits of 6–8 μm, and the average for all sections was very close to 7 μm.

5. That the RNA content is reduced in the control sections as compared with the sections prepared in the ordinary way which would result in a lower total nuclear extinction.

   This was not the case (see table 19)

6. That the staining capacity should be increased in the nuclei after treatment in phosphate buffer with and without RNase.

   This was not the case (see table 18)

7. That the calculated cytoplasmic share of the total extinction is too high. This is most likely. The calculated correction is only accurate if the cytoplasm is perfectly homogeneous, so that the extinction is proportional to the thickness of the cytoplasmic rim. The RNA in the cytoplasm is not perfectly homogeneous, but particulate, and that part of the cytoplasmic rim which lies above and below the nucleus will not participate in the total extinction to the same great extent as that part of the section which is inside the depth of focus (Einarson 1960) (see page 22)

   It is not possible to assess the magnitude of the error introduced into the calculations by this phenomenon.

The conclusion of the photometric determinations of the RNA content in the basal cell nuclei of the morphologically normal bronchial epithelium is that it is probably within the range from 1 % to 6 % of the total nucleic acid content in the nucleus, but the calculations are subject to some uncertainty

Dimensions of the Basal Nuclei

In the two groups of morphologically normal bronchial mucosae the average size of the measured nuclei was calculated (table 24)

Table 24 *Average size of the basal nuclei in the morphologically normal bronchial epithelium.*

	Diameter		
	Short μm	Long μm	Area μm²
Control group	4.58	6.16	22.2
Patients with bronchogenic carcinoma	4.62	6.47	23.5

The nuclei in the basal cell layer were not selected with a view to determining their size. Nuclei of irregular shape and excessively elongated nuclei were excluded. It is seen that the nuclei in the two groups differed only slightly in size, and the difference is not significant. It appears that the long diameter was 1.34 and 1.40 times as great as the short diameter in the two groups.

The area of the measuring field in the nuclear measurements was 4.9 μm² (see page 24), i.e., on an average it represented one quarter of the area of the nucleus. The measuring field was the largest possible which could be used for the nuclear measurements, as regard had to be paid to the short diameters of the smallest nuclei.

Table 23 *Corrected cytoplasmic extinction in the patient group with bronchogenic carcinoma*

which means that E_c constitutes

$$\frac{\frac{d-a}{d} \times E_c}{E_t} \times 100\ \%$$

of the total extinction (Swift & Rasch 1956)

That part of the total nuclear RNA content which is constituted by cytoplasmic RNA can now be calculated (tables 22 and 23)

It appears that the cytoplasmic RNA concentrations in the two patient groups constitute 5.0 % and 5.3 % of the total uncorrected nuclear RNA content. This was calculated to be 5.6 % and 6.3 % respectively of the total nuclear nucleic acid content.

If the cytoplasmic rim is perfectly homogeneous, the nuclear RNA content as a percentage of the total nucleic acid content of the nucleus will thus constitute:

5.6 % − 5.0 % = 0.6 % in the control group and
6.3 % − 5.3 % = 1.0 % in the patient group with bronchogenic carcinoma.

The figures are too small to allow a statistical comparison of the content in the two groups.

In the explanation of the low nuclear RNA content the following possibilities must be considered.

1 That actually only a small amount of RNA is present in the basal nuclei of the normal bronchial epithelium

2 That some nuclear RNA has been washed out of the nuclei during the preparation of the tissue

It is likely that a certain loss of nuclear RNA occurs during the preparation of histological sections, primarily of s-RNA which constitutes about one third of the nuclear RNA content (Amano 1967 a, 1967 b) (see page 14)

3 That some nuclear RNA is fixed so firmly by the formalin that it cannot be removed by RNase treatment

This is likely (see page 18)

4 That the average thickness of the section is not 7 µm

As mentioned on page 22, measurements of the thickness of the sections are subject to some uncertainty and in practice it is not possible to check the thickness of the sections in all areas where the cytoplasmic

1966) It seems reasonable to assume that its duration in man does not differ from that of other mammals (Lushbaugh 1956).

The mitotic index indicates the number of cells in mitosis at a given time. A high mitotic index may mean an increased number of mitoses or a prolonged mitotic time (Mazia 1961)

In adult tissue, the mitotic index will be an expression of the number of cells desquamated when no growth of the tissue occurs (Bertalanffy & Lau 196? a) Possibly the cell renewal is a protective mechanism. Many tissues are exposed to influences of various kinds, mechanical, enzymatic and bacterial. This is, however not the only cause of the cell renewal, as mitotic activity is present in various tissues which are unaffected by exogenous factors (Bertalanffy 1960) The cell renewal is a characteristic property of the tissue concerned rather than an expression of exogenous influences (Johnson 1961). After the cessation of growth, many tissues are still able to proliferate, while in others the cells have little or no ability to divide (Thrasher 1966)

The death of the host organism will prevent new cells from entering mitosis, while cells which have entered mitosis will continue this without delay (Lushbaugh 1956, Bertalanffy & Lau 196_ a) After death a steep fall in the number of mitoses occurs, and immediate fixation of the tissue is therefore of the greatest importance (Bertalanffy & Lau 1962 a). Only surgically removed tissue and biopsy specimens fixed immediately after removal are suitable for the determination of the mitotic activity (Bertalanffy 196).

The mitotic activity will show some diurnal fluctuations (Messier & Leblond 1960 Koburg & Maurer 196_) especially in slowly renewing tissues, while rapidly renewing cell systems will show only minor variations in the duration of the cell cycle and in the duration of the various phases (Thrasher 1966) Those parts of the digestive tract which are covered with columnar epithelium have no appreciable diurnal fluctuation, whereas parts covered with stratified squamous epithelium show some fluctuation, so that the mitotic activity is least after an active period and greatest after sleep (Bertalanffy 1960)

The mitotic activity may be influenced by various locally irritant or toxic substances (Bertalanffy & Lau 1962a) Prolonged fasting may also affect the mitotic activity (Hunt 1957 Hooper & Blair 1958, Bertalanffy & Lau 1962 a)

Methods of Estimation of Mitotic Activity

The mitotic activity can be estimated in different ways:

1 Counting of mitoses in fixed and stained tissue.
2. Counting of mitoses after colchicine treatment.
3 Autoradiography after treatment with radioactive thymidine (thymidine-H³).
4 Counting of cells with an increased DNA content.

Direct counting of mitoses in tissues with selection of cells in mitosis as assessed by purely morphological criteria may be beset with considerable difficulty and great uncertainty

In most tissues, the number of dividing cells is not sufficient for direct counting of mitoses to give significant data regarding cell division (Bertalanffy & Lau 1963)

Direct counting of mitoses in histological sections requires good fixation and staining. Counting of mitoses may be very difficult in tissues with small dark nuclei (Leblond et al. 1959) Mitoses can hardly be recognized in some tissues, and it may also be difficult to detect mitoses by microscopic examination (Messier & Leblond 1960, Schultze & Oehlert 1960). In neuroglia, for example, mitoses are very rarely seen. Studies with radioactive thymidine have, however shown that cell division does occur It is possible that mitoses cannot be seen on account of the small size of the cell, or the division may be atypical and im-

MITOSES

Most cells divide by mitosis, and the division comprises the cell nucleus and cytoplasm

During prophase, increasing coiling and condensation of the chromosomes take place. The nucleolus disappears, and duplication of the chromosomes into two chromatids occurs (Mazia 1961 DeRobertis et al. 1965) In early prophase, the chromosomes are evenly distributed later in prophase they approach the nuclear membrane. The mitotic spindle is formed in this phase or in metaphase. At the end of prophase the nuclear membrane disappears. At metaphase the chromosomes are disposed in the equatorial plane connected to the fibres of the mitotic spindle The chromatids move away from each other towards the poles, at the beginning of anaphase At telophase, this migration comes to an end the reconstruction of the nucleus begins the chromosomes become less compact, and the nuclear membrane is re formed. At the same time the cytoplasm is dividing.

The preparation for mitosis takes place in interphase a doubling of the DNA content occurs before visible signs of mitosis are present (Swift 1953 Patau & Swift 1953 Deeley et al 1954 Vendrely & Vendrely 1956 Deeley et al 1957 Mazia 1961)

The interphase is divided into three periods.

1 the G_1 phase or presynthetic gap
2 the S phase, in which DNA synthesis takes place and
3 the G phase or postsynthetic pause (Alpen & Johnston 1967)

During mitosis, no DNA is synthetized. The doubling of the DNA content occurs roughly along a straight line, i. e at a constant rate of synthesis (Swift 1953 Deeley et al 1957 Mazia 1961 Koburg & Maurer 1962 Maceira et al 1966) According to Alpen & Jo nston (1967), the doubling of DNA occurs along a slightly S-shaped curve, as the rate of synthesis is lower both at the beginning and at the end of the S phase. Mittermayer et al. (1968 a, 1968 b) found that the DNA synthesis was a little slower at the beginning than later in the S phase.

The time for DNA synthesis is usually stated to be of the order of 7½ hours (Thrasher 1966) with a range of variation from 6 to 9 hours (Deeley et al. 1957 Koburg & Maurer 1962 Yang et al. 1966 Maceira et al 1966, Remery et al 1967 Blenkinsopp 1968) occasionally it lasts a little longer (Lipkin et al. 1963 Stryckmans et al 1966 Blenkinsopp 1968, Mittermayer et al 1968 b)

The duration of mitosis and the rate of DNA synthesis seem to be relatively constant for a given cell type, whereas interphase and especially the G_1 phase may vary (Knowlton et al. 1950 Lushbaugh 1956 Mazia 1961 Meyer zum Gottesberge & Koburg 1963 Maceira et al 1966)

Mitosis is preceded not only by DNA synthesis, but also by a postsynthetic gap, the G_2 phase, which in man is usually shorter than the G_1 phase (Prescott 1961) A small percentage of the cells may have a deviating form of cell division in which the G_2 phase may be very long, possibly lasting for several days In mouse epidermis, 5 to 10 % of the basal cells show this form of cell division (Gelfant 1966)

The duration of mitosis in different tissues is nearly always from ½ to 3 hours (Mazia 1961) most frequently from ½ to 1 hour (Lushbaugh 1956 Bertalanffy 1964 Thrasher

Allen (1962) determined the mitotic index in most cells in the rat by counting mitoses and the cells which by *visual* evaluation had a DNA content that was twice normal. The DNA content had beforehand been measured microphotometrically in a certain number of cells. Most of them had a certain DNA content, and some cells the double content. A few cells contained an amount of DNA between these values.

Quenser et al. (1968) used microphotometric measurements of the DNA content for the determination of the mitotic index in human lymph nodes. Among a small number of cells, 104 68 and 58 respectively those with an increased DNA content outside the distribution curve for normal diploid cells were counted.

However also within the normal range of distribution for diploid cells, there will be some cells which are synthetizing DNA (Sod-Moriah et al. 1968).

By ultraviolet microphotometry Sandritter Muller et al (1958) examined scrapings of bronchial epithelial cells. The limit of normal nucleic acid content was fixed half way be t een the diploid and the tetraploid value, and the number of cells with an increased content of total nucleic acid was related to this limit. Of normal basal cells, 4 % and of ciliated cells, 14 % had a DNA content above this limit (stated for totals of 76 and 35 cells, respectively) The number of cells with an increased content of nucleic acid is remarkably high and must be taken with some reservation on account of the small number of cells studied In particular the percentage of ciliated cells seems large as DNA synthesis and mitosis should not occur in such cells.

Microphotometric measurements of the DNA content in RNase-treated, gallocyanin-chromalum-stained tissue have been used for the determination of the mitotic activity in human bronchial epithelium (Gresen 1968)

By microphotometric measurements, it is possible to find the cells with an increased DNA content a compared with normal diploid are synthetizing DNA, or in which DNA synthesis has come to an end, can be detected. This applies to cells in the S and G_2 phases of the interphase, and to cells at prophase and metaphase.

Mitotic Activity of Respiratory Epithelium

Cells which are responsible for the renewal of many tissues are chiefly of the less differentiated type, basal cells, reserve cells or germinative cells (Bertalanffy 1963).

The renewal of cells of the bronchial epithelium occurs from the basal cells. Mitoses are rarely or never seen in the highly differentiated cells (Messerklinger 1958).

Most ciliated cells are produced by mitosis in the basal cells, and this probably also applies to goblet cells. Mitoses in the differentiated cells (ciliated and goblet cells) are extremely rare, if they do occur at all (Bertalanffy 1963) Using H^3-thymidine Bindreiter et al. (1968) found that only the basal cells could accomplish division, whereas the goblet cells and ciliated cells were unable to divide. Blenkinsopp (1967) reported that when a basal cell divided, it formed one basal and one superficial cell, while a superficial cell at the same time divided into two superficial cells.

The cell renewal in the duodenum and oesophagus in mice probably occurs in such a manner that one stem cell divides, forming two stem cells, and at the same time one stem cell differentiates into a specialized cell (Thrasher 1966).

In the respiratory tract epithelium, the daily mitotic rate (the percentage of cells dividing in 24 hours) as determined by the colchicine method in the rat trachea is 2.1 % and in the bronchi 3 7 % corresponding to a total renewal of the cell population in 47 6 and 26.7 days, respectively (Bertalanffy & Lau 1962 a)

In the alveolar cells of the adult rat, Bertalanffy (1964) found a daily mitotic rate of 13.8 % and, by direct counting of mitoses in the alveolar cells, a mitotic activity of 0 48 %. For the alveolar cells, this corresponds to a duration of mitosis of about 50 minutes.

possible to recognize (Messier & Leblond 1960) The same applies to mammary epithelium (Sod Moriah et al 1968)

It may be attended with great difficulty to distinguish cells at prophase and telophase, as there is no definite morphological boundary towards the G_2 and the G_1 phase of interphase Of the cells in *mitosis, 70–80 % will be at* prophase or telophase, and on account of this it is understandable that direct counting of mitoses at least in many tissues, is beset with considerable uncertainty (Bertalanffy 1964)

In the epithelium of the small intestine, the mitotic activity is very brisk and in this field a number of investigations utilizing direct counting of the mitoses have been performed (Leblond & Stevens 1948 Bertalanffy & Nagy 1961 Padykula et al 1961)

On exposure to the action of colchicine or related substances, mitosis is arrested at meta phase By counting the number of metaphases in a tissue, its mitotic activity can be assessed. Colchicine inhibits the formation of the mitotic spindle. The chromatids are then unable to move away from each other In addition, substances inhibiting the spindle formation induce a contraction of the chromosomes, which renders them even more distinct under the mi croscope (*Östergren 1944 Ludford 1953 Hsu* 1961)

If the dose of colchicine is too large this will result in cell destruction inhibition of the *mitotic activity (Lushbaugh 1956)* and inhibi tion of DNA synthesis (Gustafsson 1968)

On *the other hand,* a too small dose of colchicine will prevent division of only some of the cells, and the inhibition of mitosis will be only transient (Lushbaugh 1956 Bertalanffy & Lau 1962 a) If a suitable dose is admin istered neither stimulation nor depression of the mitotic activity nor affection of DNA syn thesis, will occur (Bloch 1953 Bertalanffy & Leblond 1953 Hooper 1961 Gelfant 1963 Bertalanffy 1964)

By mitotic counts after colchicine treatment, the number of cells dividing in 24 hours, and hence the rate of renewal of *the tissue may* be calculated (Bertalanffy 1963)

Colcemide which is less toxic and more effective than colchicine, has been used for the determination of the mitotic activity in man (Laavåg 1967)

Thymidine H^3 is most commonly used for autoradiographic determinations of the mitotic ac tivity Cells specifically incorporate thymidine during the synthesis of DNA which is then stable (Amano et al 1959 Thrasher 1966)

Radioactive thymidine exerts a biological effect on dividing cells, and at the same time expose them to irradiation. Thymidine H^3 may increase the duration of metaphase, suppress DNA synthesis and delay cell division (Thrasher 1966 Yang et al. 1966 Fakan 1969)

The method is mainly of importance in ani mal experiments and in tissue cultures. In man the method can usually not be applied in vivo because of irradiation hazards (Oliver et al. 1960 Johnson et al 1961) In a few patients with incurable cancers, the mitotic activity has, however been determined after administration of labelled thymidine (Johnson et al 1960 Cole & *McKalen 1961 Lipkin et al. 1963)*

After in-vitro incorporation of H^3-thymidine *the mitotic activity can be determined in biopsy* specimens (Fabrikant & Cherry 1969) Some *reluctance must, however* be recommended in the evaluation of DNA synthesis in removed tissue (cf page 45) (Bertalanffy & Lau 1962 a Bertalanffy 1962)

By the thymidine H^3 method the cells which incorporate radioactive thymidine during the synthesis of DNA in the S phase are revealed

Cells which at a given moment have an in creased DNA content as compared with a nor mal diploid cell population can be distin guished by photometric measurements.

Cells with DNA values in the range of twice the normal *diploid value are presumed to be* cells synthetizing DNA in preparation for mi *tosis (Queisser et al 1966)*

Allen (1962) determined the mitotic index in mast cells in the rat by counting mitoses and the cells which by visual evaluation had a DNA content that was twice normal. The DNA content had beforehand been measured microphotometrically in a certain number of cells. Most of them had a certain DNA content, and some cells the double content. A few cells contained an amount of DNA between these values.

Quesser et al. (1968) used microphotometric measurements of the DNA content for the determination of the mitotic index in human lymph nodes. Among a small number of cells, 104 68 and 58, respectively those with an increased DNA content outside the distribution curve for normal diploid cells were counted.

However also within the normal range of distribution for diploid cells, there will be some cells which are synthetizing DNA (Sod-Moriah et al. 1968).

By the thymidine-H^3 method the cells which incorporate radioactive thymidine during the synthesis of DNA in the S phase are revealed

Cells which at a given moment have an increased DNA content as compared with a normal diploid cell population can be distinguished by photometric measurements.

Cells with DNA values in the range of twice the normal diploid value are presumed to be cells synthetizing DNA in preparation for mitosis (Queisser et al 1966)

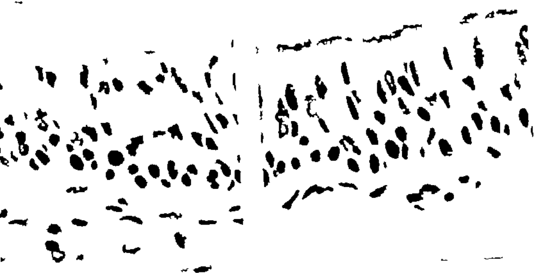

Fig. 11

Fig. 12.

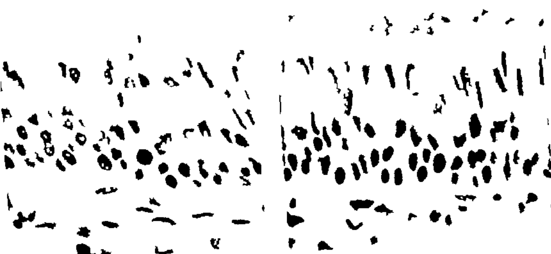

Fig. 13.

Fig. 14

Hyperdiploid cell nuclei in normal bronchial epithelium (RNase gallocyanin-chromalum, × 715).

doubled DNA content in preparation for mitosis would be distributed around the double of the diploid mean with the same scatter (Fig. 15).

By photometric methods it will not be possible to detect the cells which have just begun to synthetize DNA or which are close to the diploid distribution curve. Only cells with a DNA content of about $1^1/_2$ × the mean or more can be distinguished from cells with a basal diploid DNA content. In the measurements on these hyperdiploid cells the mean of the DNA content was calculated in 20 normal basal nuclei in RNase-treated sections. An arbitrary limit was fixed at $1^1/_2$ × the mean. All nuclei which seemed to contain an amount of

On the assumption that the duration of mitosis in the trachea and bronchi is the same as in the alveolar cells, it can be calculated from these figures that the number of mitoses at a given moment in the trachea and bronchi will be 0 07 and 0 13 % respectively ($2\ 1 \times 0\ 48$ 13 8 and $3\ 7 \times 0\ 48$ 13 8) If it is assumed that the duration of synthesis is about 7 times as long as that of mitosis (Thrasher 1966) 0 49 and 0 91 % of the cells will be in the S phase

As good agreement between the mitotic activity in human tissue and in rat tissue has been disclosed, both in duodenal epithelium (Leblond & Stevens 1948 Bertalanffy & Nagy 1961) and rectal epithelium (Bertalanffy 1960 Cole & McKalen 1961) it is reasonable to assume that the mitotic activity in the human bronchial mucosa is of the same order as in the rat.

After one dose of H^3-thymidine, 0 40–0 50 % labelled cells were found in the tracheal epithelium of the rat (Messier & Leblond 1960) After H^3-thymidine, other investigators have found 1 72 % labelled cells in the major bronchi, and 0 53 % in the minor bronchi (Koburg 1960 1962, Meyer zum Gottesberge & Koburg 1963)

H^3-thymidine will be available for the synthesis of DNA for 3/4 to 1 hour (Koburg 1960 Mazia 1961) The labelled cells will be an expression of the cells incorporating H^3-thymidine in DNA during that period i.e cells in the S phase plus cells which have entered the G_2 phase within 3/4 to 1 hour

Personal Investigations

In morphologically normal bronchial epithelium the basal cell nuclei are small and dark with a dense chromatin structure. Cells in mitosis cannot be observed in formalin-fixed biopsy specimens of normal bronchial epithelium.

In spite of the homogenizing effect of formalin on the nuclear chromatin (see page 21) direct counting of mitoses have however been carried out in various formalin-fixed tissues (Bertalanffy & Nagy 1961 Hunt 1957 Dörmer et al 1964 Greenwood et al. 1968 Morgan et al 1968) The type of tissue used is probably of decisive importance (Leblond et al 1959 Messier & Leblond 1960)

It must be regarded as unquestionable that cell renewal occurs in human bronchial epithelium However potential hazards are involved in studying the mitotic activity in healthy human beings by the use of colchicine or related chemical agents, or by radioactive substances. On the other hand such studies can be performed on human bronchial mucosae—without any pretreatment—by means of photometric determinations (Greisen 1968).

In the study of the DNA content of the nuclei in the basal cell layer of the bronchial epithelium a few nuclei with an increased content of DNA were observed. These nuclei were darker and larger than the normal basal nuclei (figs. 11 12 13 and 14)

About one half of the cells with increased DNA content were found in the deepest part in the basal cell layer close to the basement membrane, while the other half were situated just superficial to the most basal cell layer On the other hand, no cells with increased DNA content were found in the more differentiated cells in the superficial cell layer

By counting the cells with increased DNA content, the number of cells which are synthetizing DNA or which have doubled the DNA content in preparation for mitosis, can be assessed.

By the determination of the DNA content in 20 to 30 nuclei after exclusion of those with a distinctly elevated DNA content, there will be only a slight risk of a positive skewness of the distribution curve of the DNA content in the diploid cells, because the mitotic activity in the bronchial epithelium is comparatively low (Atkin et al. 1966)

The DNA content will be distributed around a mean with only a little scatter (average coefficient of variation 8 7 %) If this was due exclusively to errors of measurements, cells with

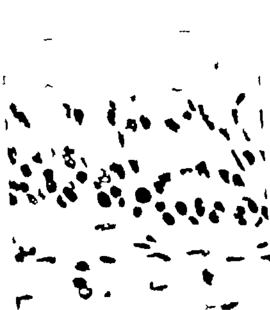

Fig. 11

On the assumption that the duration of mitosis in the trachea and bronchi is the same as in the alveolar cells it can be calculated from these figures that the number of mitoses at a given moment in the trachea and bronchi will be 0 07 and 0 13 % respectively (2.1 × 0 48 13 8 *and* 3 7 × 0 48 13 8) *If it is as*sumed that the duration of synthesis is about 7 times as long as that of mitosis (Thrasher 1966) 0 49 and 0 91 % of the cells will be in the S phase.

As good agreement between the mitotic activity in human tissue and in rat tissue has been disclosed both in duodenal epithelium (Leblond & Stevens 1948 Bertalanffy & Nagy 1961) and rectal epithelium (Bertalanffy 1960 Cole & McKalen 1961) it is reasonable to assume that the mitotic activity in the human bronchial mucosa is of the same order as in the rat.

After one dose of H^3*-thymidine,* 0 40–0.50 % labelled cells were found in the tracheal epithelium of the rat (Messier & Leblond 1960) After H^3-thymidine, other investigators have found 1 72 % labelled cells in the major bronchi, and 0.53 % in the minor bronchi (Koburg 1960 1962, Meyer zum Gottesberge & Koburg 1963)

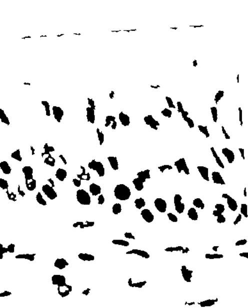
H^3-thymidine will be available for the synthesis of DNA for 3/4 to 1 hour (Koburg 1960 Mazia 1961) The labelled cells will be an expression of the cells incorporating H^3-thymidine in DNA during that period, i e cells in the S phase plus cells which have entered the G_2 phase within 3/4 to 1 hour

Personal Investigations

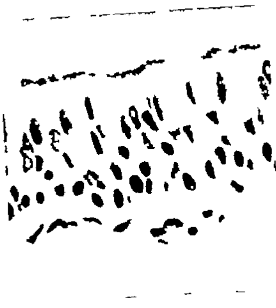
In morphologically normal bronchial epithelium, the basal cell nuclei are small and dark with a dense chromatin structure. Cells in mitosis cannot be observed in formalin fixed biopsy specimens of normal bronchial epithelium.

In spite of the homogenizing effect of formalin on the nuclear chromatin (see page 21) direct counting of mitoses have however been carried out in various formalin fixed tissues (Bertalanffy & Nagy 1961 Hunt 1957 Dörmer et al 1964 Greenwood et al 1968 Morgan et al 1968) The type of tissue used is probably of decisive importance (Leblond et al 1959 Messier & Leblond 1960)

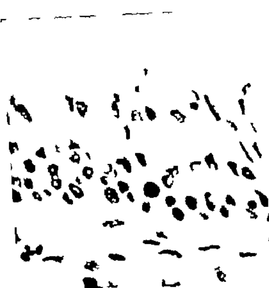
It must be regarded as unquestionable that cell renewal occurs in human bronchial epithelium. However potential hazards are involved in studying the mitotic activity in healthy human beings by the use of colchicine or related chemical agents, or by radioactive substances. On the other hand, such studies can be performed on human bronchial mucosae—without any pretreatment—by means of photometric determinations (Greisen 1968)



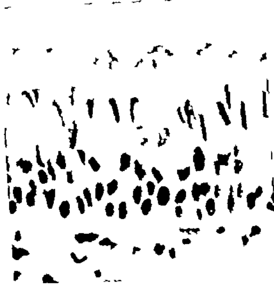
In the study of the DNA content of the nuclei in the basal cell layer of the bronchial epithelium a few nuclei with an increased content of DNA were observed. These nuclei *were darker and larger than the normal basal* nuclei (figs. 11 12 13 and 14)



About one half of the cells with increased DNA content were found in the deepest part in the basal cell layer close to the basement membrane, while the other half were situated just superficial to the most basal cell layer On the other hand no cells with increased DNA content were found in the more differentiated cells in the superficial cell layer



By counting the cells with increased DNA content, the number of cells which are synthetizing DNA or which have doubled the DNA content in preparation for mitosis, can be assessed



By the determination of the DNA content in 20 to 30 nuclei after exclusion of those with a distinctly elevated DNA content there will be only a slight risk of a positive skewness of the distribution curve of the DNA content in the diploid cells, because the mitotic activity in the bronchial epithelium is comparatively low (Atkin et al 1966)

The DNA content will be distributed around a mean with only a little scatter (average coefficient of variation 8 7 %) If this was due exclusively to errors of measurements cells with

Hyperdiploid cell nuclei in normal bronchial epithelium (RNase, gallocyanin-chromalum, × 715).

oubled DNA content in preparation for mitosis would be distributed around the double of the diploid mean with the same scatter (fig. 5).

By photometric methods it will not be possible to detect the cells which have just begun to synthetize DNA or which are close to the diploid distribution curve. Only cells with a DNA content of about 1 / × the mean or more can be distinguished from cells with a basal diploid DNA content. In the measurements on these hyperdiploid cells the mean of the DNA content was calculated in 20 normal basal nuclei in RNase-treated sections. An arbitrary limit was fixed at $1^1/_2$ × the mean. All nuclei which seemed to contain an amount of

On the assumption that the duration of mitosis in the trachea and bronchi is the same as in the alveolar cells, it can be calculated from these figures that the number of mitoses at a given moment in the trachea and bronchi will be 0 07 and 0 13 % respectively (2.1 × 0 48 13 8 and 3 7 × 0 48 13 8) If it is assumed that the duration of synthesis is about 7 times as long as that of mitosis (Thrasher 1966) 0 49 and 0 91 % of the cells will be in the S phase

As good agreement between the mitotic activity in human tissue and in rat tissue has been disclosed, both in duodenal epithelium (Leblond & Stevens 1948 Bertalanffy & Nagy 1961) and rectal epithelium (Bertalanffy 1960 Cole & McKalen 1961) it is reasonable to assume that the mitotic activity in the human bronchial mucosa is of the same order as in the rat.

After one dose of H^3-thymidine, 0 40–0.50 % labelled cells were found in the tracheal epithelium of the rat (Messier & Leblond 1960) After H^3-thymidine, other investigators have found 1 72 % labelled cells in the major bronchi, and 0.53 % in the minor bronchi (Koburg 1960 1962, *Meyer zum Gottesberge* & Koburg 1963)

H^3-thymidine will be available for the synthesis of DNA for ³/₄ to 1 hour (Koburg 1960 Mazia 1961) The labelled cells will be an expression of the cells incorporating H^3-thymidine in DNA during that period, i e cells in the S phase plus cells which have entered the G_2 phase within ³/₄ to 1 hour

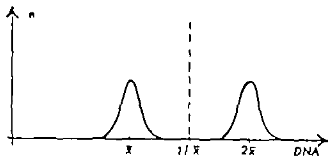

Fig. 15.—Distribution of DNA content in diploid and tetraploid nuclei in normal bronchial epithelium

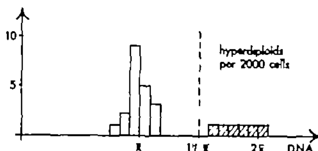

Fig. 16.—Distribution of DNA content in normal and hyperdiploid nuclei in normal bronchial epithelium (section No 59).

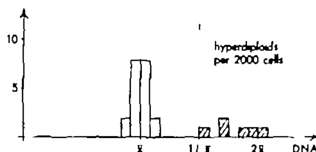

Fig. 17.—Distribution of DNA content in normal and hyperdiploid nuclei in normal bronchial epithelium (section No 55).

DNA above the content in the normal diploid cell nuclei were measured. All cells which in subsequent calculations had a DNA content of 1½ × the mean or more were stated as hyperdiploid cells (figs. 16 and 17).

The number of hyperdiploid cells is stated per 2,000 superficial and basal cells in the bronchial epithelium. In a few cases, however, they are stated for a figure less than 2,000, viz. when an insufficient number of nuclei were present in the section.

The mitotic activity was determined in the following groups:

1. Patients with normal bronchial mucosa and benign disease unrelated to the bronchial tree (control group).
2. Morphologically normal bronchial mucosa from patients with bronchogenic carcinoma.

In the original biopsy material the average age of the patients in the control group was 44.3 years as compared with 61.3 years in the second group.

To obtain more comparable groups as regards age and to examine a larger number of specimens, the original material was supplemented by biopsy specimens obtained from the Institute of Pathology. Group 1 was supplemented by specimens from patients with uveitis, group 2 by specimens from patients with bronchogenic carcinoma. An attempt was made to select elderly patients for group 1 and younger for group 2.

Tables 25 and 26 show the age distribution, average DNA content and number of hyperdiploid cells in the two groups.

It appears that there is only a slight difference in the average ages of the two groups, and that there is no difference in the average mitotic activity in normal bronchial epithelium in the control group and the group with bronchogenic carcinoma elsewhere in the bronchial mucosa.

A homogeneous cell population with a certain DNA value will, in preparation for mitosis, synthetize DNA until twice the original value is reached. Provided that the mitotic activity

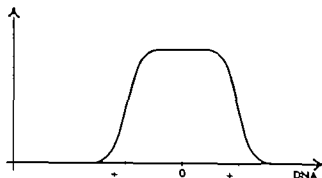

Fig. 19 —DNA content in synthetizing cells (see text)

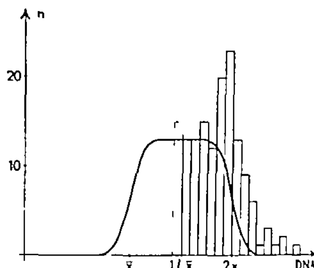

Fig. 20 —Distribution of hyperdiploid cell nuclei in morphologically normal bronchial epithelium

normal distribution function Figure 19 shows graphically the appearance of g (x n) In the figure, n = 6 which roughly corresponds to an average diploid DNA content of 12 in the normal nuclei, and a standard deviation of 1

After DNA synthesis there is however a postsynthetic pause, during which the cells have a tetraploid content of DNA This is manifested by an accumulation of cells with the tetraploid DNA content in the distribution curve.

The DNA content of the hyperdiploid cell nuclei in different sections cannot be directly compared As appears from tables 25 and 26 the diploid mean differs in the various sections. If the DNA content of the hyperdiploid cell nuclei is calculated in relation to a diploid mean of 12 A U the DNA content in the cells can be compared.

In the morphologically normal bronchial mucosae a total of 132 hyperdiploid cell nuclei were found These were distributed as shown in figure 20

If the hyperdiploid cell nuclei in the metaplastic mucosae are included the number increases to 257 (fig. 21)

It appears from figures 20 and 21 that, after a certain level there will be an accumulation of hyperdiploid cells around the tetraploid

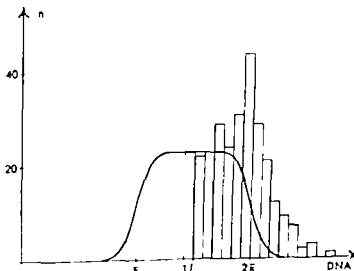

Fig 21 —Distribution of hyperdiploid cell nuclei in normal and metaplastic bronchial epithelium

value. If the cells divided immediately after the cessation of synthesis, the curve would assume a form as shown in figure 19 It can be seen from the curve that, of the 132 hyper diploid cells in the normal mucosae, 77 are inside the area that would be expected if the cells divided immediately whereas the accumulation of cells with the tetraploid value comprises 55 cell nuclei. As the curve in figure 19 is symmetrical around the mid-line, 77 cell nuclei must also be located to the left of the value $1^1/_2 \times$ the mean, corresponding to about 60 % (77 132 $\times$ 100)

When the normal bronchi contained a number of hyperdiploid cell nuclei corresponding to 0.3 % of the total number the total of cells which at a given moment are, or have been, synthetizing DNA will be 60 % higher i.e. about 0.48 % This number is of the same order as that stated for the mitotic activity in the respiratory epithelium in animals.

Conclusions

By means of microphotometry it has proved possible, in a simple way to investigate the mitotic activity in a tissue.

The method is harmless as no pre-treatment of the tissue is required. There is no need for planning the investigation beforehand, and older blocks of biopsy specimens can be used.

The investigation was carried out on human bronchial epithelium, in which the mitotic activity has not previously been studied.

The investigation revealed that there was no difference in the mitotic activity in the normal bronchial epithelium from a control group and a group of patients with bronchogenic carcinoma elsewhere in the bronchial mucosa. This means that disturbances in the mitotic activity in morphologically normal bronchial mucosae cannot be demonstrated prior to the development of precancerous changes.

METAPLASTIC BRONCHIAL EPITHELIUM

By metaplasia is understood the tranformation from one well-defined type of epithelium to another In the bronchial epithelium, meta plasia indicates the presence of transitional or stratified squamous epithelium. Basal-cell hy perplasia and atypical epithelial changes are, however usually also included in the meta plastic changes of the bronchial mucosa (Na sell 1963)

Metaplasia is caused by various factors, such as infections or damage of a chemical or phy sical nature During the development of meta plasia, normal epithelium passes through vari- ous phases The epithelium first shows an in- crease in the number of goblet cells (Spencer 1962) The formation of transitional epithelium may occur through a phase of splitting of the epithelium with formation of a slit between the basal-cell layer and the overlying col umnar-cell layer which shows different de- grees of degenerative changes, or through a phase of basal-cell hyperplasia (Nasiell 1963) Basal-cell hyperplasia may be defined as a condition with more than two layers of basal cells (Auerbach et al. 1956)

Through these phases, true metaplastic epi thelium develops, either transitional epithelium which is the most common or stratified squa mous epithelium Morphologically transitional epithelium is similar to the urinary tract epi- thelium. It is without cilia on the surface, and consists of several layers of polygonal cells, possibly with a few layers of flat cells on the surface. In stratified squamous epithelium there is a more pronounced flattening of the cells The transition from one type to the other occurs gradually (Nasiell 1963)

Through a stage of atypical epithelium car cinoma *in situ develops*. The atypical epithe lium is hypercellular and consists of polymor phic cells with hyperchromatic nuclei and an irregular chromatin pattern. In carcinoma in situ, the cellular atypia is more pronounced and occurs in all layers of the epithelium. The cells are carcinoma-like, but show no signs of invasive growth. Atypical epithelial changes and carcinoma in situ are almost exclusively found in metaplastic epithelium (Nasiell 1968 a, 1968 c)

It is presumed that the malignant neoplastic condition has a long preceding stage with mor phological changes in the cells of the epithe- lium and that carcinoma represents the final stage. These antecedent epithelial changes may be diffuse, while the invasive carcinoma in- volves only a limited area. The precancerous changes in the bronchial epithelium are cellular atypia and carcinoma in situ preceded by metaplasia. However the extent to which metaplasia and precancerous cell atypia de velop in parallel or to which metaplasia pre- cedes the atypical changes in the cells is un- known It is generally believed that metaplasia occurs first, and metaplasia without atypical cells is therefore not regarded as a pre- cancerous alteration (Nasiell 1968 c)

Most authors assume that metaplastic changes play an important part in the develop- ment of bronchogenic carcinoma and the view has repeatedly been expressed that there is a relation between metaplastic changes and lung cancer (Auerbach et al 1956 Auerbach et al. 1957 a, Valentine 1957 Nasiell 1968 a) in such a manner that bronchogenic carcinoma is preceded by these changes.

Metaplasia possibly promotes carcinogenesis In areas without cilia, the transport of secre tion is slow and they will therefore be partic

ularly exposed to an intensified action of carcinogens (Hilding 1956)

If the factors producing metaplasia are not combined with the carcinogenic factors which produce atypical cells, there is no risk of the development of carcinoma. The risk of malignant alterations increases with the extent of the metaplastic changes, because epithelium with metaplastic changes is more susceptible to carcinogenic influences than normal respiratory epithelium. Definitely atypical epithelium is virtually never encountered in normal respiratory pseudo-stratified columnar epithelium. Most frequently the atypical changes are seen as localized alterations within a wide spread area with metaplastic epithelium (Nasiell 1968 b).

Metaplastic changes in the bronchial epithelium, the preceding degenerative alterations in the columnar epithelium and atypical metaplasia occurred much more frequently in a series of squamous-cell carcinomata and undifferentiated carcinomata than in a control group and a group with adenocarcinomata (Hackensellner 1957 b, Nasiell 1963) The high incidence of metaplasia in squamous-cell carcinoma and undifferentiated carcinoma indicates that exogenous factors are responsible for the development of metaplasia, and that these alterations in the bronchial epithelium presumably constitute the basis for the development of squamous-cell carcinoma and undifferentiated carcinoma (Nasiell 1968 a) These findings are also in agreement with the assumption that adenocarcinoma of the bronchi to a lesser degree than squamous-cell carcinoma and undifferentiated carcinoma is associated with exogenous factors (Nasiell 1963 1966, 1967 Maamies 1966)

Auerbach et al. (1956, 1957 a) studied the occurrence of pathological changes in the bronchial epithelium in relation to smoking. The frequency of basal-cell hyperplasia, metaplastic changes and carcinoma in situ increased with the use of tobacco. The alterations were most pronounced in the patients who died of lung cancer Ford et al. (1961) found similar evidence, although they could not confirm that carcinoma in situ was more frequent in smokers. Chang (1957) showed that the occurrence of metaplasia and atypical epithelium was more frequent in smokers than in non-smokers. In a cytological material, the incidence of metaplastic changes and atypical metaplasia in the columnar epithelium was considerably higher in smokers than in non-smokers (Nasiell 1968 b)

It seems beyond doubt that there is a causal relationship between smoking and bronchogenic carcinoma (Watson & Conte 1954 Hackensellner 1957 a, Clemmesen 1961 Ministry of Health 1961) Other exogenous factors may however be a contributory cause for example inhalation of various chemical agents (Liebow 1952, Wilkins et al. 1957 Hackensellner 1957 a) It has been shown experimentally that in mice exposed to tobacco smoke hyperplastic alterations in the bronchial epithelium, with atypical changes, will develop (Leuchtenberger et al. 1958 Leuchtenberger et al. 1963) and that metaplastic changes and carcinomata of the respiratory tract may be produced in certain animals after oral administration of diethylnitrosamine (Dontenwill et al. 1961 a, 1961 b)

In a study of 54 cases of bronchogenic carcinoma (squamous-cell, 33 undifferentiated, 16 alveolar-cell, 3 and malignant cylindromata, 2) Auerbach et al. (1957 b) found carcinoma in situ or atypical changes in the bronchial epithelium in 48 cases. In 43 of 51 cases these alterations were also present in the opposite lung. The clinical significance is that cases which are regarded as recurrences or metastases are probably often carcinomata which have developed in the areas with premalignant changes. Carcinoma in situ or fully developed carcinoma of other locations in the bronchial tree were also reported by Black & Ackermann (1952), Ford et al. (1961) and Spencer (1968)

Mitotic Activity

In basal-cell hyperplasia, the mitotic activity in the bronchial epithelium is increased (Black

Chapter 5

METAPLASTIC BRONCHIAL EPITHELIUM

By metaplasia is understood the tranformation from one well-defined type of epithelium to another In the bronchial epithelium metaplasia indicates the presence of transitional or stratified squamous epithelium Basal-cell hyperplasia and atypical epithelial changes are, however usually also included in the metaplastic changes of the bronchial mucosa (Nasiell 1963)

Metaplasia is caused by various factors, such as infections or damage of a chemical or physical nature During the development of metaplasia, normal epithelium passes through various phases. The epithelium first shows an increase in the number of goblet cells (Spencer 1962) The formation of transitional epithelium may occur through a phase of splitting of the epithelium with formation of a slit between the basal-cell layer and the overlying columnar-cell layer which shows different degrees of degenerative changes, or through a phase of basal-cell hyperplasia (Nasiell 1963) Basal-cell hyperplasia may be defined as a condition with more than two layers of basal cells (Auerbach et al. 1956)

Through these phases, true metaplastic epithelium develops, either transitional epithelium which is the most common, or stratified squamous epithelium Morphologically transitional epithelium is similar to the urinary tract epithelium It is without cilia on the surface and consists of several layers of polygonal cells, possibly with a few layers of flat cells on the surface. In stratified squamous epithelium, there is a more pronounced flattening of the cells The transition from one type to the other occurs gradually (Nasiell 1963)

Through a stage of atypical epithelium carcinoma in situ develops. The atypical epithelium is hypercellular and consists of polymorphic cells with hyperchromatic nuclei and an irregular chromatin pattern. In carcinoma in situ the cellular atypia is more pronounced and occurs in all layers of the epithelium The cells are carcinoma-like but show no signs of invasive growth. Atypical epithelial changes and carcinoma in situ are almost exclusively found in metaplastic epithelium (Nasiell 1968 a, 1968 c)

It is presumed that the malignant neoplastic condition has a long preceding stage with morphological changes in the cells of the epithelium and that carcinoma represents the final stage. These antecedent epithelial changes may be diffuse while the invasive carcinoma involves only a limited area The precancerous changes in the bronchial epithelium are cellular atypia and carcinoma in situ preceded by metaplasia. However the extent to which metaplasia and precancerous cell atypia develop in parallel, or to which metaplasia precedes the atypical changes in the cells is unknown. It is generally believed that metaplasia occurs first, and metaplasia without atypical cells is therefore not regarded as a precancerous alteration (Nasiell 1968 c)

Most authors assume that metaplastic changes play an important part in the development of bronchogenic carcinoma and the view has repeatedly been expressed that there is a relation between metaplastic changes and lung cancer (Auerbach et al 1956 Auerbach et al 1957 a, Valentine 1957 Nasiell 1968 a) in such a manner that bronchogenic carcinoma is preceded by these changes.

Metaplasia possibly promotes carcinogenesis In areas without cilia, the transport of secretion is slow and they will therefore be partic

activity with a large formation of proteins (Caspersson 1947).

The present author has previously published a study of the concentrations of cytoplasmic RNA in metaplastic and morphologically normal bronchial mucosae (Greisen 1968).

Personal Investigations

Nuclear Measurements

The average content of DNA in metaplastic bronchial epithelium has in previous studies been related to that observed in normal diploid nuclei (Leuchtenberger et al. 1958, Bonani & Gandolfi 1961, Leuchtenberger et al. 1963). In comparison with normal epithelium, the average content of DNA in metaplastic epithelium was found to be increased. An explanation of this increase was not given. From tables in the two above-mentioned studies by Leuchtenberger et al. it is seen that there are both a greater dispersion of the values towards higher values,

& Ackermann 1952 Valentine 1957) Cunningham (1959) found that, in basal-cell hyperplasia actual mitoses were rare, but nuclei twice as large as normal were occasionally seen.

In animal experiments with H³-thymidine Dontenwill & Wiebecke (1964) observed considerably more labelled cells in metaplastic than in normal bronchial mucosae. The number of labelled cells increased with the degree of metaplasia In the fully developed carcinoma, the mitotic activity was of the same order as in the cases of severe metaplasia. The normal bronchi contained 0 85 ‰ labelled cells, but with increasing degrees of metaplasia the number rose to 15 48 69 and 58 ‰

In the study of tobacco-exposed mice, Leuchtenberger et al. (1958 1963) found no visible mitoses in the bronchial epithelium in a control group and only a few in a group with slight hyperplastic changes, whereas there were a larger number of mitoses in a group with more pronounced proliferative changes.

In experimental studies of the carcinogenic influence on the epidermis, the mitotic activity was found to increase from normal epidermis through various degrees of hyperplastic changes to the fully developed carcinoma (Kiljunen 1956 Dörmer et al 1964) The duration of DNA synthesis was of about the same order in normal skin hyperplastic skin and in carcinoma of the skin (Dörmer et al 1964)

Photometric Investigations

Boriani & Gandolfi (1961) studied the DNA content in human bronchi with varying degrees of metaplasia and found an average increase in the DNA content, especially in the basal nuclei, in parallel with the severity of the metaplasia. The distribution of the DNA values in the individual sections was not reported in the study

Microphotometric investigations of the bronchial mucosa in mice did not show any difference in the DNA content in the nuclei in morphologically normal mucosae exposed to cigarette smoke and a control group On the other hand it was observed that an average increase in the volume of the nuclei and an increase in the nuclear content of protein occurred in the cigarette-exposed animals before morphological changes developed in the epithelium. The average content of nuclear DNA increased with the degree of metaplasia (Leuchtenberger et al 1958 Leuchtenberger et al 1963).

Grundmann et al. (1961 a) made microphotometric measurements of the DNA content in the epithelial cells of the vaginal portion of the uterus both under normal conditions and through various degrees of epithelial changes to the fully developed carcinoma. In normal and slightly abnormal epithelium the DNA values were found mainly around a basal diploid value with some values in the range up to twice that figure.

The irregular and atypical epithelium revealed mainly tetraploid, or even higher values, whereas a still greater dispersion of the values was seen in the carcinoma In a comparison of DNA determinations performed on Feulgen-stained sections and nucleic acid determinations carried out on gallocyanin-chromalum-stained sections (Grundmann et al 1961 b) it appeared that the transition from normal to abnormal epithelium was accompanied by an increased RNA content of the basal cells. However in the study of these relatively thick sections, no regard was paid to cytoplasmic RNA which would be expected to increase with the atypia of the epithelium

As compared with normal the atypical epithelium revealed an increased cytoplasmic RNA content in the irregular and pre invasive stages (Grundmann et al 1960) Similar observations were made by Tsanev et al (1960) during the development of carcinoma of the skin. The cytoplasmic basophilia caused by RNA was found to be increased in precancerous conditions and in fully developed carcinomata of the skin as compared with normal epidermis.

The increased cytoplasmic content of RNA may be taken as evidence of increased cellular

Fig. 22.—Metaplastic bronchial epithelium (gallocyanin-chromalum, × 350).

Fig. 23.—Metaplastic bronchial epithelium (RNase, gallocyanin-chromalum, × 350).

activity with a large formation of proteins (Caspersson 1947).

The present author has previously published a study of the concentrations of cytoplasmic RNA in metaplastic and morphologically normal bronchial mucosae (Greisen 1968).

Personal Investigations

Nuclear Measurements

The average content of DNA in metaplastic bronchial epithelium has in previous studies been related to that observed in normal diploid nuclei (Leuchtenberger et al. 1958, Boriani & Gandolfi 1961, Leuchtenberger et al. 1963). In comparison with normal epithelium, the average content of DNA in metaplastic epithelium was found to be increased. An explanation of this increase was not given. From tables in the two above-mentioned studies by Leuchtenberger et al. it is seen that there are both a greater dispersion of the values towards higher values,

Fig. 24.—Metaplastic bronchial epithelium (gallocyanin-chromalum, × 560).

Fig. 25.—Metaplastic bronchial epithelium (RNase gallocyanin chromalum, × 560).

and a displacement of the peak of the distribution curve towards higher values.

To investigate the distribution of the DNA values in metaplastic bronchial epithelium, the DNA content was measured in 30 nuclei. The large and dark nuclei with an obvious hyperdiploid content were excluded just as in the nuclear measurements on morphologically normal bronchial mucosae. As most of the cells exhibited this basal diploid value, it was not difficult to segregate the hyperdiploid cell group, even though considerably more hyperdiploid cells were present in metaplastic bronchial mucosae than in normal ones (see page 59).

Some sections contained not only metaplastic, but also morphologically normal epithelium (table 27).

From the table it appears that there is only a slight difference in the content of nucleic

acid of diploid nuclei in the metaplastic and the normal epithelium in the same section. The difference in the nuclear content of DNA + RNA is smaller than reflected by the figures in the table, because the measurements of DNA + RNA were performed on non-RNase-treated sections in which the cytoplasmic RNA content will result in a greater extinction in metaplastic than in normal mucosae. However it will be difficult to avoid a slight uncertainty in the determination of the basal diploid value in metaplastic mucosae, with a tendency to a higher average value than normal, on account of the brisker mitotic activity

Measurements of the nuclear content of RNA will be difficult because the technique is beset with various limitations. The shape and orientation of the nuclei are not as regular as in normal bronchial epithelium, and the cytoplasmic extinction varies in the different layers of metaplastic mucosae. In addition, the determination of the basal diploid value in metaplastic mucosae is more difficult on account of the greater mitotic activity which tends to give a wider dispersion of the DNA values.

After the determination of the basal diploid value in the metaplastic epithelium, the number of hyperdiploid cells was counted. As in the morphologically normal bronchial mucosae, the limit for the hyperdiploid cells was fixed at 1½ × the mean of the diploid value. After the determination of the DNA content in all cell nuclei which appeared to be large and/or dark in comparison with the diploids, all nuclei with a calculated DNA content exceeding 1½ × the mean were put down as hyperdiploid. The number of hyperdiploid cells is stated per 500 cell nuclei. As distinct from the normal bronchial epithelium, in which no mitoses were seen, a few mitoses were found in the metaplastic epithelium. The DNA content in these nuclei was measured to be at about the tetraploid value. Figure 26 shows an example of the measurements of the DNA content in a metaplastic epithelium.

The number of hyperdiploid cell nuclei is stated in table 28

As already mentioned, the mitotic activity in metaplastic bronchial mucosae is increased. It is seen from figures 21 and 26 that the DNA content in the hyperdiploid cells is dis-

tributed in the range from the basal diploid value to twice that figure One cell nucleus was found with a DNA content twice the tetraploid value It was a nucleus at prophase with incipient condensation of the nuclear chromatin (section No 55 atypical metaplasia) In all other sections the values of the nuclei were up to but not higher than twice the diploid value and might be accepted as cells which were synthetizing DNA in preparation for mitosis. The mitotic activity observed in the metaplastic epithelium is in good agreement with the results of the investigations with radioactive thymidine in metaplastic bronchial epithelium (Dörmer et al 1964) However there is no conclusive proof that all cells with a hyperdiploid content of DNA are synthetizing DNA Some of the hyperdiploid cells might have an aneuploid content of DNA

The distribution curve for the hyperdiploid cells is nevertheless in favour of the assumption that the cell nuclei are synthetizing DNA If the DNA content just as in the hyperdiploid nuclei in normal bronchial mucosae, is related to a mean of 12 A U and the distribution is plotted for the hyperdiploid nuclei the resulting curve will be similar to the distribution curve for the hyperdiploid nuclei in morphologically normal mucosae (the octaploid cell nucleus which was found in one section with atypical metaplasia is included as two tetraploid nuclei) (figs. 20 and 21)

It can be seen from the distribution curve (fig. 21) that the mitotic activity in the metaplastic epithelium just as in normal bronchial epithelium is about 55 % larger than the number of hyperdiploid cell nuclei suggests. The number of all synthetizing cells in the metaplastic mucosae is thus, on an average, about 4 8 %

If all the hyperdiploid cells observed can be taken as cells synthetizing DNA the mitotic activity in metaplastic mucosae will be 4 8 % as against 0 48 % in morphologically normal bronchial mucosae i e the mitotic activity is 10 times as large as in normal bronchial epithelium.

The metaplastic epithelium showed basal-cell hyperplasia (sections Nos. 37 41 44) simple metaplasia (sections Nos. 58 61 62) and atypical metaplasia (sections Nos. 55 57).

The average percentages of hyperdiploid cells were 2 9 % 2 9 % and 3 9 % respectively The material is too small to assess the number of hyperdiploid cells in the various degrees of metaplasia

Cytoplasmic Measurements

In the evaluation of the RNA concentration in metaplastic bronchial epithelium the cytoplasmic extinction was measured (1) around the basal cells, (2) in the intermediate layer and (3) in the cytoplasm of the superficial cell layer For each of the three layers, the cytoplasmic extinction is stated as the average of 50 measurements.

Before the measurements on the cytoplasm were performed the content of mucopolysaccharides, if any was assessed by PAS staining. Only in a single section with basal-cell hyperplasia were there so many mucin-secreting cells in the superficial cell layer that the cytoplasmic content of RNA could not be assessed with certainty

After treatment with RNase the cytoplasmic extinction was measured in the basal, intermediate and superficial cell layers. Each figure for the RNase-treated sections represents the average of 15 measurements In the determination of the cytoplasmic extinction it is the concentration of RNA which is measured The volume of the cytoplasm is, however most likely larger in metaplastic epithelium than in the basal cells of morphologically normal bronchial epithelium It therefore appears certain that there is an increase not only in the concentration of RNA but also in its content in metaplastic epithelium (figs. 4 8 9 22 24)

The series of metaplastic mucosae studied consisted of eight biopsy specimens from the original material supplemented by nine biopsy specimens from the Institute of Pathology (table 29)

After treatment with RNase the intense cy

The average for the entire material of metaplastic epithelium was 0.26, as against 0 17 in the morphologically normal mucosae. Figure 27 shows the concentration of RNA in metaplastic and normal mucosae.

In eight sections, the epithelium showed basal-cell hyperplasia, in six cases simple metaplasia, and in three atypical metaplasia. The average concentrations of RNA in the three groups were 0.26, 0.25 and 0.28 respectively The differences are not significant.

Conclusions

The metaplastic bronchial mucosae differ from the normal ones with regard to the nucleic acid content in nuclei and cytoplasm.

Like normal epithelium, the metaplastic mucosae contain a population of cells with diploid nuclei, but, as compared with the normal ones, they also have a considerably increased number of hyperdiploid nuclei, viz. 10 times as many This is presumably due to cells which are synthetizing DNA in preparation for mitosis, even though it cannot be excluded that some of the cells may have an increased aneuploid DNA content. The nuclear content of DNA does not show as might be expected from the results of previous investigations, a gradual increase in the DNA content of the cell nuclei. In the metaplastic mucosae there is, as in the normal mucosae, not only a basal diploid stem cell, but also an increased number of cell nuclei with a hyperdiploid DNA content.

tributed in the range from the basal diploid value to twice that figure One cell nucleus was found with a DNA content twice the tetraploid value It was a nucleus at prophase with incipient condensation of the nuclear chromatin (section No 55 atypical metaplasia) In all other sections, the values of the nuclei were up to, but not higher than twice the diploid value, and might be accepted as cells which were synthetizing DNA in preparation for mitosis. The mitotic activity observed in the metaplastic epithelium is in good agreement with the results of the investigations with radioactive thymidine in metaplastic bronchial epithelium (Dörmer et al 1964) However there is no conclusive proof that all cells with a hyperdiploid content of DNA are synthetizing DNA. Some of the hyperdiploid cells might have an aneuploid content of DNA.

The distribution curve for the hyperdiploid cells is nevertheless in favour of the assumption that the cell nuclei are synthetizing DNA If the DNA content, just as in the hyperdiploid nuclei in normal bronchial mucosae, is related to a mean of 12 A U and the distribution is plotted for the hyperdiploid nuclei, the resulting curve will be similar to the distribution curve for the hyperdiploid nuclei in morphologically normal mucosae (the octaploid cell nucleus which was found in one section with atypical metaplasia is included as two tetraploid nuclei) (figs. 20 and 21)

It can be seen from the distribution curve (fig. 21) that the mitotic activity in the metaplastic epithelium, just as in normal bronchial epithelium is about 55 % larger than the number of hyperdiploid cell nuclei suggests. The number of all synthetizing cells in the metaplastic mucosae is thus, on an average, about 4 8 %

If all the hyperdiploid cells observed can be taken as cells synthetizing DNA the mitotic activity in metaplastic mucosae will be 4 8 % as against 0 48 % in morphologically normal bronchial mucosae i. e the mitotic activity is 10 times as large as in normal bronchial epithelium.

The metaplastic epithelium showed basal cell hyperplasia (sections Nos. 37 41 44) simple metaplasia (sections Nos. 58 61 62) and atypical metaplasia (sections Nos. 55 57)

The average percentages of hyperdiploid cells were 2 9 % 2 9 % and 3 9 % respectively The material is too small to assess the number of hyperdiploid cells in the various degrees of metaplasia.

Cytoplasmic Measurements

In the evaluation of the RNA concentration in metaplastic bronchial epithelium, the cytoplasmic extinction was measured (1) around the basal cells, (2) in the intermediate layer and (3) in the cytoplasm of the superficial cell layer For each of the three layers, the cytoplasmic extinction is stated as the average of 50 measurements.

Before the measurements on the cytoplasm were performed the content of mucopolysaccharides, if any was assessed by PAS staining. Only in a single section with basal-cell hyperplasia were there so many mucin secreting cells in the superficial cell layer that the cytoplasmic content of RNA could not be assessed with certainty

After treatment with RNase the cytoplasmic extinction was measured in the basal intermediate and superficial cell layers. Each figure for the RNase-treated sections represents the average of 15 measurements. In the determination of the cytoplasmic extinction, it is the concentration of RNA which is measured. The volume of the cytoplasm is, however most likely larger in metaplastic epithelium than in the basal cells of morphologically normal bronchial epithelium It therefore appears certain that there is an increase not only in the concentration of RNA but also in its content in metaplastic epithelium (figs. 4 8 9 22 24)

The series of metaplastic mucosae studied consisted of eight biopsy specimens from the original material supplemented by nine biopsy specimens from the Institute of Pathology (table 29)

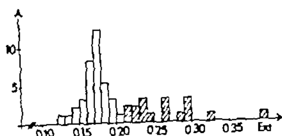

Fig. 27.—Distribution of the average cytoplasmic RNA concentration in metaplastic bronchial epithelium (hatched columns) and in normal bronchial epithelium (white columns).

The average for the entire material of metaplastic epithelium was 0.26 as against 0.17 in the morphologically normal mucosae. Figure 27 shows the concentration of RNA in metaplastic and normal mucosae.

In eight sections, the epithelium showed *basal-cell hyperplasia*, in six cases simple metaplasia, and in three atypical metaplasia. The average concentrations of RNA in the three groups were 0.26, 0.25 and 0.28 respectively. The differences are *not significant*.

Conclusions

The metaplastic bronchial mucosae differ from the normal ones with regard to the nucleic acid content in nuclei and cytoplasm.

Like normal epithelium, the metaplastic mucosae contain a population of cells with diploid nuclei, but, as compared with the normal ones, they also have a considerably increased number of *hyperdiploid nuclei*, viz. 10 times as many. This is presumably due to cells which are synthetizing DNA in preparation for mitosis, even though it cannot be excluded that some of the cells may have an increased aneuploid DNA content. The nuclear content of DNA does not show as might be expected from the results of previous investigations, a gradual increase in the DNA content of the cell nuclei. In the metaplastic mucosae there is, as in the *normal* mucosae, not only a basal diploid stem cell, but also an increased number of cell nuclei with a hyperdiploid DNA content.

The cytoplasmic concentration and most likely also the cytoplasmic content of RNA are considerably increased in comparison with the basal cells of morphologically normal bronchial epithelium

It appears that only when morphological alterations in the form of metaplasia have occurred in the bronchial epithelium can changes in its nucleic acid content be demonstrated, viz. an increase both in the number of hyper diploid cells and in the concentration of RNA in the cytoplasm

BRONCHIAL ADENOMA

Bronchial adenoma covers two different types of tumours, viz. the carcinoid tumour and the cylindroma, which differ in histological structure and secretory properties.

The carcinoid tumours comprise 90 % of the adenomata, while the remaining 10 % are cylindromata. The tumours are nearly always localized in the large bronchi, and 90 % of them can be seen through the bronchoscope. The adenoma is equally frequent in the two sexes. It occurs in all age groups, even in children (Kreyberg 1962, 1967). The average age of the patients is within the range of 44–48 years.

The cylindromata arise from the mucous glands in the bronchial mucosa. This is evidenced by their resemblance with other mucous-gland tumours, the production of mucin, and the absence of these tumours in the periphery where the bronchial mucosa does not contain glands. The origin of the carcinoid tumours is more disputable, and many theories of their origin have been advanced. Histologically they have many features in common with the tumours of the same name in the digestive tract, and, like the latter, they probably arise from argentaffine cells in the epithelium or from neurosecretory cells in the mucous glands (Spencer 1962, 1968). Engelbreth-Holm (1944) expressed the view that there was no reason to segregate a special group of adenomata as cylindromata, as cylindroid portions may develop both in bronchial adenomata and in various other epithelial tumours. Clinically the carcinoid syndrome may be seen in bronchial carcinoid tumours as well as in the carcinoids of the intestine (Weiss et al. 1961).

The adenoma is growing either as a bronchial polyp or as an infiltrating submucous tumour (Spencer 1962).

Histologically the carcinoid tumour is composed of small, uniform cells with regularly rounded or slightly oval nuclei with evenly distributed fine chromatin granules. The cells grow in solid cords, in trabeculae, or show a glandlike structure. Mitoses are rarely seen (Liebow 1952, Kreyberg 1962, Spencer 1962).

The cylindromata are, although to a different extent, mucin-producing. Most commonly the shape of the cell does not differ from that of the normal gland cells, but there may be various degrees of anaplasia. The cells grow in trabeculae or tubes, which may contain PAS-positive mucin. Mitoses are here more frequent than in the carcinoid tumours.

The adenoma is usually a benign tumour. It grows slowly and spreads mainly by local invasion. Lymphogenic metastases occur in less than one half of the cases and are usually late. In less than 2 % there is haematogenic extension (Liebow 1952, Kreyberg 1962, Spencer 1962).

Nucleic Acid Determinations

Only a few studies of the DNA content and chromosomes in benign tumours are available.

Stich et al. (1960) investigated the DNA content in normal epithelium, in histologically benign polyps and in adenocarcinomata of the large intestine. No polyploid cell nuclei were found in the normal epithelium of the intestine, i. e. no cell nuclei with a DNA content higher than twice the basal diploid value. Among eight histologically benign polyps, two revealed metaphases with a DNA content twice as large as that of the metaphases in the diploid class,

The cytoplasmic concentration, and most likely also the cytoplasmic content of RNA are considerably increased in comparison with the basal cells of morphologically normal bronchial epithelium

It appears that only when morphological alterations in the form of metaplasia have occurred in the bronchial epithelium can changes in its nucleic acid content be demonstrated, viz. an increase both in the number of hyperdiploid cells and in the concentration of RNA in the cytoplasm

BRONCHIAL ADENOMA

Bronchial adenoma covers two different types of tumours, viz. the carcinoid tumour and the cylindroma, which differ in histological structure and secretory properties.

The carcinoid tumours comprise 90 % of the adenomata, while the remaining 10 % are cylindromata. The tumours are nearly always localized in the large bronchi, and 90 % of them can be seen through the bronchoscope. The adenoma is equally frequent in the two sexes. It occurs in all age groups, even in children (Kreyberg 1962, 1967). The average age of the patients is within the range of 44–48 years.

The cylindromata arise from the mucous glands in the bronchial mucosa. This is evidenced by their resemblance with other mucous-gland tumours, the production of mucin, and the absence of these tumours in the periphery where the bronchial mucosa does not contain glands. The origin of the carcinoid tumours is more disputable, and many theories of their origin have been advanced. Histologically they have many features in common with the tumours of the same name in the digestive tract, and, like the latter they probably arise from argentaffine cells in the epithelium or from neurosecretory cells in the mucous glands (Spencer 1962, 1968). Engelbreth-Holm (1944) expressed the view that there was no reason to segregate a special group of adenomata as cylindromata, as cylindroid portions may develop both in bronchial adenomata and in various other epithelial tumours. Clinically the carcinoid syndrome may be seen in bronchial carcinoid tumours as well as in the carcinoids of the intestine (Weiss et al. 1961).

The adenoma is growing either as a bronchial polyp or as an infiltrating submucous tumour (Spencer 1962).

Histologically the carcinoid tumour is composed of small, uniform cells with regularly rounded or slightly oval nuclei with evenly distributed fine chromatin granules. The cells grow in solid cords, in trabeculae, or show a glandlike structure. Mitoses are rarely seen (Liebow 1952, Kreyberg 1962, Spencer 1962).

The cylindromata are, although to a different extent, mucin-producing. Most commonly the shape of the cell does not differ from that of the normal gland cells, but there may be various degrees of anaplasia. The cells grow in trabeculae or tubes, which may contain PAS-positive mucin. Mitoses are here more frequent than in the carcinoid tumours.

The adenoma is usually a benign tumour. It grows slowly and spreads mainly by local invasion. Lymphogenic metastases occur in less than one half of the cases and are usually late; in less than 2 % there is haematogenic extension (Liebow 1952, Kreyberg 1962, Spencer 1962).

Nucleic Acid Determinations

Only a few studies of the DNA content and chromosomes in benign tumours are available.

Stich et al. (1960) investigated the DNA content in normal epithelium, in histologically benign polyps and in adenocarcinomata of the large intestine. No polyploid cell nuclei were found in the normal epithelium of the intestine, i.e. no cell nuclei with a DNA content higher than twice the basal diploid value. Among eight histologically benign polyps, two revealed metaphases with a DNA content twice as large as that of the metaphases in the diploid class,

i. e. the cells had a modal value within the tetraploid range. In all the remaining cases, the *modal value was within the diploid range*, although it was a little higher than the basal somatic diploid value in the lymphocytes. As distinct from the wide dispersion of the values in the adenocarcinoma due to an aneuploid number of chromosomes there was only a slight dispersion of the metaphase values in the polyps.

Jacobsen (1968) studied the nucleic acid content in benign prostatic adenomata and found a slightly increased average content of DNA + RNA as compared with nuclei in normal prostatic epithelium. The dispersion around the *mean was greater than in the normal nuclei* of the prostate. In terms of arbitrary units, the nucleic acid content was 9.1 A. U. in normal nuclei, and 10.5 A. U. in the adenomata.

In microphotometric studies of mammary tumours, Emson et al. (1967) found a DNA content of only up to twice the diploid value in cystic hyperplasia. In the intraductal carcinoma with uniform cell types, values up to the tetraploid value were also found while a wider dispersion with values above the tetraploid value was revealed in the comedo carcinoma. In the adenocarcinoma, the DNA content showed a wide dispersion, with many values above the tetraploid level.

Similar observations were made by Bader et al. (1960) in a study of ovarian tumours. In benign tumours, DNA values above twice the basal value were not found, and the determinations of the DNA content indicated that mitotic irregularities were either absent or of very slight importance for the DNA content of benign and slightly malignant tumours.

In benign tumours of the thyroid, Garneau (1964) found a modal value at the diploid level determined by a comparison with the DNA content of lymphocytes.

In chromosome studies of benign tumours a normal diploid number of chromosomes was observed in virus induced papillomata. On the other hand after malignant transformation the carcinomata which developed were characterized by a hyperdiploid modal number of chromosomes (Hsu 1961). Palmer (1959) likewise reported that most cells in virus induced papillomata had a diploid number of chromosomes.

Chromosome studies on adenomata of the colon revealed some pseudodiploid nuclei and many aneuploid metaphases, yet with only small deviations from normal values. Most metaphases were hyperdiploid. Abnormal individual chromosomes were rare in the adenomata (Enterline et al. 1967).

In a group of mammary tumours, chromosome studies showed normal diploid metaphases in benign cystic hyperplasia, while the cells in carcinomata revealed a diploid modal number in two cases, a triploid in five, and a pentaploid number of chromosomes in one (Toews et al. 1968).

Only a few investigations of the nucleic acid content of bronchial adenomata are available. In a series of biopsy specimens from the bronchi Boriani & Gandolfi (1961) made microphotometric measurements of the DNA content of carcinoid tumours after Feulgen staining. The number of adenomata studied was not stated. The average content of DNA in the adenomata was a little higher than in the nuclei of normal bronchial epithelium. The histograms are narrow with only a slight dispersion, and the values are grouped symmetrically around one value. The adenomata differed clearly from the malignant bronchial neoplasms not only in the smaller average content of DNA in the nuclei but also in the very slight dispersion of the values.

Seidel & Sandritter (1963) studied microphotometrically the DNA content in a cystic lung adenoma and a case of malignant lung adenomatosis (alveolar-cell carcinoma). The distribution of the nuclear DNA values in the cystic lung adenoma showed a maximum at the diploid value. The values were dispersed up to, but not above the tetraploid level. Cells with these values were probably in the premitotic stage synthetizing DNA.

In the cytoplasm of papillomata of the

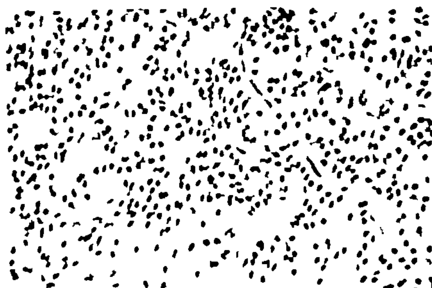

Fig. 21.—Bronchial adenoma (carcinoid) (gallocyanin-chromalom, 350)

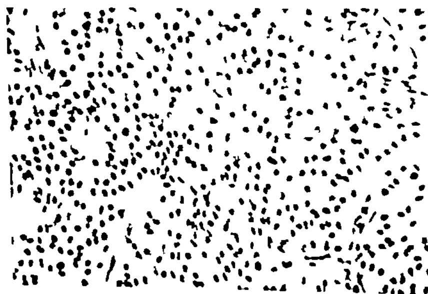

Fig. 22.—Bronchial adenoma (carcinoid) (RNase, gallocyanin-chromalom, 350)

bladder Caspersson & Santesson (1942) found an increasing concentration of cytoplasmic RNA from benign through more malignant to fully developed carcinoma cells. No investigations of the cytoplasmic concentration of RNA in bronchial adenomata or other benign tumours seem to be on record.

Mitoses

In microscopic studies of tissue from bronchial adenomata, none or only a few mitoses are found in the carcinoid tumours, while mitoses are more frequent in the cylindroma (Engelbreth-Holm 1944, Liebow 1952, Kreyberg 1962, Spencer 1962).

No reports on the mitotic activity in bronchial adenomata exist, and on the whole only a few studies of the mitotic activity in benign tumours are available.

In studies with H^3-thymidine, Johnson et al. (1960) found that the mitotic activity in a

i e the cells had a modal value within the tetraploid range. In all the remaining cases, the modal value was within the diploid range although *it was a little higher than the basal* somatic diploid value in the lymphocytes As distinct from the wide dispersion of the values in the adenocarcinoma due to an aneuploid number of chromosomes, there was only a slight dispersion of the metaphase values in the polyps

Jacobsen (1968) studied the nucleic acid content in benign prostatic adenomata and found a slightly increased average content of DNA + RNA as compared with nuclei in normal prostatic epithelium The dispersion around the mean was greater than in the normal nuclei of the prostate. In terms of arbitrary units the nucleic acid content was 9 1 A U in normal nuclei and 10 5 A U in the adenomata.

In microphotometric studies of mammary tumours, Emson et al (1967) found a DNA content of only up to twice the diploid value in cystic hyperplasia In the intraductal carcinoma with uniform cell types, values up to *the tetraploid value were also found* while a wider dispersion with values above the tetraploid value was revealed in the comedo carcinoma. In the adenocarcinoma, the DNA content showed a wide dispersion, with many values above the tetraploid level

Similar observations were made by Bader et al (1960) in a study of ovarian tumours In benign tumours, DNA values above twice the basal value were not found, and the determinations of the DNA content indicated that mitotic irregularities were either absent or of very slight importance for the DNA content of benign and slightly malignant tumours

benign ovarian cystadenoma was of the same order as in normal skin while it was less pronounced in a scirrhous mammary tumour from the same patient.

That the mitotic activity does not directly depend on the degree of malignancy of the tumour appears from a study of mammary cancer published by Johnson et al in 1961 The mitotic activity was of the same order in a normal duct and in carcinoma cells, whereas it was three times as high in a fibro-adenoma

Personal Investigations

The material studied consisted of 14 biopsy specimens of bronchial adenomata secured from eight patients. The sections A 2, A 3 and A 16 are from different sites of the same tumour whereas sections A 9 A 10 A 11 A 13 and A 17 are all cylindromata originating from the same patient. The biopsies were performed at intervals of a few weeks or months.

Cylindromata are usually more malignant

than carcinoid tumours. The cylindromata in this material all revealed a benign histological structure and the clinical course was also benign.

Nuclear Measurements

Determination of the nucleic acid content in the nuclei was performed in the same way as in the normal bronchial mucosae. In each of the non-RNase-treated sections, the nucleic acid content was measured in 30 nuclei. In the RNase-treated sections, in 20 nuclei. The measurements of the total nuclear nucleic acid content included a small amount of cytoplasmic RNA (table 31).

The total nuclear nucleic acid content averaged 12.1 A. U (as compared with 12.6 A. U in the normal epithelial nuclei). The dispersion of the means in the sections (from 9.7 to 16.1 A. U.) is a little greater than in the normal epithelium, which may probably be ascribed to the more unequal treatment of these biopsy specimens (fig. 32).

The average DNA content in the nuclei is of the same order as in the normal nuclei (see page 34).

The modal value of the bronchial adenomata was determined as follows: The DNA content of the tumour stem cell was related to that of the normal diploid nuclei in the section,

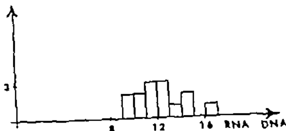

Fig. 32.—Distribution of the average nuclear nucleic acid content in bronchial adenomata.

i.e. in nuclei of normal bronchial epithelium, if such were present, or in lymphocytes, which are nearly always present in the sections (Ricards *et al.* 1956, Atkin & Richards 1956, Bader 1959 Stich et al. 1960, Seidel & Sandritter 1963 Garneau 1964 Atkin et al. 1966, Emson & Kirk 1967).

In photometric measurements, it is possible to determine the modal value with reasonable certainty in nearly all tumours. Many nuclei are grouped around a basal value, sometimes with a distinct secondary accumulation of results at twice or perhaps, four times the basal value (Atkin *et al.* 1966).

The position of the modal value is stated in relation to the diploid or near-diploid, triploid or near-triploid, and tetraploid or near tetraploid values. The limits were fixed so that the ratios between modal and diploid values were in the range from 0.75 to 1.25 from 1.25 to 1.75 and from 1.75 to 2.25 respectively (Wakonig Vaartaja et al. 1967) (table 32).

In agreement with previous studies on modal values in benign tumours, it appeared that the modal values in nearly all bronchial adenomata were within the diploid or near-diploid range. Only in one case was it within the *near-triploid range* (section No. A 4).

The number of hyperdiploid nuclei in the bronchial adenomata was determined in the same way as in the normal and the metaplastic bronchial epithelium (fig. 33).

The number of hyperdiploid nuclei is stated per 1000 tumour nuclei (table 33).

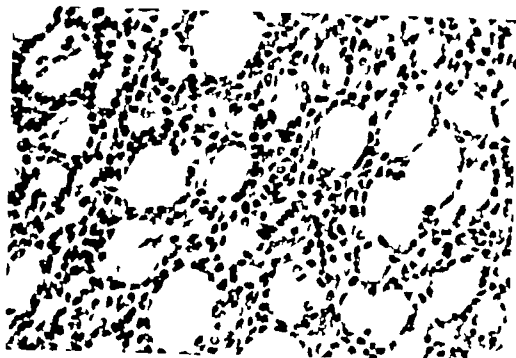

Fig. 30.—Bronchial adenoma (cylindroma) (gallocyanin-chromalum, × 350).

Fig. 31.—Bronchial adenoma (cylindroma) (RNase gallocyanin chromalum, × 350).

of the cytoplasmic RNA concentrations (table 34).

From table 34 it appears that the average cytoplasmic extinction is of the same order as in normal bronchial epithelium. There is a certain variation in the values around the mean. Only in one case a cylindroma, was a distinctly increased concentration of cytoplasmic RNA, 0.30 revealed, while the other cylindromata did not show any difference as compared with the carcinoid tumours. The distribution of the average cytoplasmic extinction appears from figure 34

Fig 34—Distribution of the average cytoplasmic RNA concentration in bronchial adenomata.

Conclusions

The average values of the nuclear nucleic acid content in the adenomata were of the same order as in normal epithelial nuclei. The modal value was in just one case within the triploid range, while in all other cases, they were within the diploid or near-diploid range. The number of hyperdiploid cell nuclei was, probably as an expression of mitotic activity three times as large as in normal bronchial epithelium. With one exception, the extinction of the cytoplasm was as in normal bronchial epithelium.

The adenomata thus differ from normal bronchial epithelium in having a larger number of hyperdiploid cells. An elevated modal value was observed in one case and an increased cytoplasmic RNA concentration in one. On the other hand, the adenomata differ distinctly from carcinomata in that there is only a small dispersion of the values of the nuclear nucleic acid content, and the DNA content does not exceed twice the basal modal value.

It appears that the average number of hyperdiploid nuclei in the bronchial adenomata is about three times as large as in the normal bronchial epithelium and about three times as low as in the metaplastic mucosa.

It is likely that the hyperdiploids are synthetizing DNA in preparation for mitosis. No nuclei were found in the range from above twice the modal value, and most nuclei were around the basal modal value. In the microphotometric investigations, however, it could not be excluded that some nuclei with a hyperdiploid DNA content might be aneuploid.

From table 33 it appears that there may be quite an appreciable variation in the number of hyperdiploid nuclei in various places of the same tumour (sections Nos. A 2, A 3, A 16). A repetition of the measurements gave the same results.

It is also seen that the average percentage of hyperdiploid nuclei was 0 54 in the cylindromata as against 1 47 in the carcinoid tumours.

As, histologically, the cylindroma usually shows more malignant features than the carcinoid tumours, a larger number of hyperdiploid cell nuclei might be expected in the former. However, the histological structure of the cylindromata in the present series and the clinical course were benign, and the material is too small to allow a statistical comparison.

Cytoplasmic Measurements

The measurements of the cytoplasmic RNA concentrations in the adenomata were, as in the other tissues, performed at 570 nm. The results are calculated as an average of 50 measurements performed in one or two places per cell, depending on the density of the cells. Measurements of the extinction were also carried out on connective tissue of the tumours and, in the RNase treated sections, on the cytoplasm of the tumour cells and the connective tissue of the tumours. A few adenomata contained scattered PAS-positive material. These places were avoided during the determination

with about the same frequency centrally (36 %) and peripherally (33 %)

The growth of squamous-cell carcinoma may be relatively slow and metastases are often confined to regional lymph nodes. The development of small-celled anaplastic carcinoma is more rapid with a greater tendency to distant metastases, which are not infrequently the presenting symptom (Kreyberg 1962). Slowly growing tumours often have a higher rate of operability and a better prognosis than rapidly proliferating and rapidly metastasizing tumours (Andersen et al. 1969)

Lymph-node metastases occur more often in the small-celled anaplastic carcinoma than in the two other types (Nohl 1962, Jepsen 1966)

A considerably greater extrapulmonary dissemination of tumour cells was also reported by Maamies (1966) in cases of small-celled anaplastic carcinoma as distinct from squamous-cell carcinoma and adenocarcinoma (41.3 % 26.1 % and 0.5 % respectively) This dissemination is associated with a grave prognosis (Watson 1958, Nohl 1962, Hukill et al. 1962)

Growth into the large pulmonary vessels, especially *the veins,* is a very grave prognostic sign (Collier et al. 1957 Spencer 1968)

The size and the localization of the tumour are also assumed to be of substantial importance in the prognosis. Most of the small tumours are central, and will produce symptoms at an early stage, while the larger tumours are mostly found peripherally indicating that the symptoms occur at a later stage in the development of the disease (Walter & Pryce 1955 b). The fact that so many bronchogenic tumours are peripheral contributes to the poor prognosis (Walter & Pryce 1955 b) On the other hand, peripheral tumours are more often operable than the central ones, which is a good sign as far as the prognosis is concerned (Andersen et al. 1969)

Various studies have shown that the prognosis is most favourable for squamous-cell carcinoma, just as good or nearly so for adenocarcinoma, while it is much graver for small-celled anaplastic carcinoma (Kirklin et al. 1955 Boucot et al 1959 Watson & Berg 1962, Goldman 1965 Hyde et al. 1965 Maamies 1966 Jones et al. 1967)

Many factors are thus of importance in the prognosis of bronchogenic carcinoma, the histological type of tumour its localization, its tendency to haematogenic or lymphogenic spread, its growth into blood vessels, and its growth rate.

As far as bronchogenic carcinomata are concerned, it has also been revealed that the type of carcinoma with the best prognosis contains the largest number of polyploid cell nuclei (Greisen 1969)

Nucleic Acid Content

The nucleus of the cancer cell often differs from that of the normal cell nuclei in shape, size and staining capacity

The shape and the size are more variable than in normal cell nuclei. The shape is often more irregular and the nucleus of the cancer cell is usually larger than that of the normal cell. *None of these changes are, however specific* for the cancer cell (Oberling & Bernhard 1961)

Caspersson & Santesson (1942) described two different types of cancer cells. In type A, the nucleus is of normal or slightly increased size. The *nucleus* contains a large amount of DNA, and there is a distinct, but not particularly large, *nucleolus*. Type-A cells are mainly found peripherally in the tumour tissue, around the vessels and infiltrating the connective tissue, where the most favourable nutritive conditions exist. In type B, the nucleus is considerably larger with a smaller content of DNA, and with a large nucleolus containing a large *amount of* RNA. This cell type is found mainly in the central part of a tumour the more central the cell is, the more typical it becomes. From type B there is a gradual transition to necrotic cells, which contain a still smaller amount of DNA.

By chemical determinations of the content of nucleic acids in a number of tumours, Wüst

Chapter 7

BRONCHOGENIC CARCINOMA

Pathological Anatomy

The three most common and best defined bronchogenic carcinomata are the squamous-cell carcinoma, the small-celled anaplastic carcinoma and the adenocarcinoma, mentioned in the order of decreasing frequency. The large-celled anaplastic carcinomata are not so well defined; most of these can by various histochemical procedures, be grouped either under squamous-cell carcinomata or particularly under adenocarcinomata (Kreyberg 1962, Maamies 1966).

Epidermoid or squamous-cell carcinoma is the designation for the type which shows stratification of the cells, intercellular bridges, wheel formation or keratinization (Kreyberg 1962, Spencer 1968).

The small-celled anaplastic carcinoma is characterized by small spheric to oval cells with very sparse cytoplasm. The cells are usually grouped in clusters or cords without stratification. Many mitoses are often seen. The basal, morphological criterion for the adenocarcinoma is the glandular structure with or without mucin.

The use of tobacco, especially cigarette smoking, and other exogenous factors are important causal factors in the development of epidermoid carcinoma and small-celled anaplastic carcinoma, whereas the frequency of the adenocarcinoma is not significantly increased by excessive smoking (Liebow 1952, Kreyberg 1962).

Bronchogenic carcinoma rarely occurs before the age of 30–39 years, and its frequency increases steeply with advancing age.

In most cases, especially as far as squamous-cell and small-celled anaplastic carcinomata are concerned, the surface epithelium seems to be the site of origin of the tumour. Presumably adenocarcinoma also arises from the surface epithelium (Jonas & Hukill 1968). Gradual transition from atypical stratified squamous epithelium to carcinoma in situ and manifest carcinoma may occur (Liebow 1952). It is usually assumed that most bronchogenic carcinomata arise from the epithelium covering the bronchi and bronchioles. Probably they develop from the basal cells, which are able to differentiate into cells which differ in function and structure (Walter & Pryce 1955 a).

Squamous-cell carcinoma arises from foci of squamous-cell metaplasia, adenocarcinoma from atypical cylindrical cells or from mucous glands, while small-celled anaplastic carcinoma is presumed to develop from basal cells of the bronchial epithelium (Watson & Berg 1962, Spencer 1968).

One third of the squamous-cell carcinomata, three quarters of the adenocarcinomata and one fifth of the small-celled anaplastic carcinomata arise in the periphery of the bronchial system (Spencer 1968). Maamies (1966) found that of squamous-cell carcinomata 63 % were central, 22 % intermediate and 15 % peripheral. The corresponding figures for adenocarcinomata were 44 %, 30 % and 25 %, and for small-celled anaplastic carcinoma 74 %, 20 % and 6 % respectively. In a group of resected tumours, Walter & Pryce (1955 b) found that squamous-cell carcinoma occurred more frequently centrally (44 %) than peripherally (28 %), while adenocarcinoma was most commonly localized peripherally (84 %) and that small-celled anaplastic carcinoma occurred

with about the same frequency centrally (36 %) and peripherally (33 %)

The growth of squamous-cell carcinoma may be relatively slow and metastases are often confined to regional lymph nodes. The development of small-celled anaplastic carcinoma is more rapid with a greater tendency to distant metastases, which are not infrequently the presenting symptom (Kreyberg 1962) Slowly growing tumours often have a higher rate of operability and a better prognosis than rapidly proliferating and rapidly metastasizing tumours (Andersen et al. 1969)

Lymph-node metastases occur more often in the small-celled anaplastic carcinoma than in the two other types (Nohl 1962, Jepsen 1966)

A considerably greater extrapulmonary dissemination of tumour cells was also reported by Maamies (1966) in cases of small-celled anaplastic carcinoma as distinct from squamous-cell carcinoma and adenocarcinoma (41.3 % 26.1 % and 20.5 % respectively) This dissemination is associated with a grave prognosis (Watson 1958, Nohl 1962, Hukill et al. 1962)

Growth into the large pulmonary vessels, especially the veins, is a very grave prognostic sign (Collier et al. 1957 Spencer 1968)

The size and the localization of the tumour are also assumed to be of substantial importance in the prognosis. Most of the small tumours are central, and will produce symptoms at an early stage, while the larger tumours are mostly found peripherally indicating that the symptoms occur at a later stage in the development of the disease (Walter & Pryce 1955 b) The fact that so many bronchogenic tumours are peripheral contributes to the poor prognosis (Walter & Pryce 1955 b) On the other hand, peripheral tumours are more often operable than the central ones, which is a good sign as far as the prognosis is concerned (Andersen et al. 1969)

Various studies have shown that the prognosis is most favourable for squamous-cell carcinoma, just as good or nearly so for adenocarcinoma, while it is much graver for small-celled anaplastic carcinoma (Kirklin et al. 1955 Boucot et al. 1959 Watson & Berg 1962, Goldman 1965 Hyde et al. 1965 Maamies 1966, Jones et al. 1967)

Many factors are thus of importance in the prognosis of bronchogenic carcinoma. the histological type of tumour its localization, its tendency to haematogenic or lymphogenic spread, its growth into blood vessels, and its growth rate.

As far as bronchogenic carcinomata are concerned, it has also been revealed that the type of carcinoma with the best prognosis contains the largest number of polyploid cell nuclei (Greisen 1969)

Nucleic Acid Content

The nucleus of the cancer cell often differs from that of the normal cell nuclei in shape, size and staining capacity

The shape and the size are more variable than in normal cell nuclei. The shape is often more irregular and the nucleus of the cancer cell is usually larger than that of the normal cell. None of these changes are, however specific for the cancer cell (Oberling & Bernhard 1961)

Caspersson & Santesson (1942) described two different types of cancer cells. In type A, the nucleus is of normal or slightly increased size. The nucleus contains a large amount of DNA, and there is a distinct, but not particularly large, nucleolus. Type-A cells are mainly found peripherally in the tumour tissue, around the vessels and infiltrating the connective tissue, where the most favourable nutritive conditions exist. In type B, the nucleus is considerably larger with a smaller content of DNA, and with a large nucleolus containing a large amount of RNA. This cell type is found mainly in the central part of a tumour the more central the cell is, the more typical it becomes. From type B, there is a gradual transition to necrotic cells, which contain a still smaller amount of DNA.

BRONCHOGENIC CARCINOMA

Pathological Anatomy

The three most common and best defined bronchogenic carcinomata are the *squamous-cell carcinoma, the small-celled* anaplastic carcinoma and the adenocarcinoma, mentioned in the order of decreasing frequency The large celled anaplastic carcinomata are not so well defined most of these can, by various histochemical procedures, be grouped either under squamous-cell carcinomata or particularly under adenocarcinomata (Kreyberg 1962 Maamies 1966)

Epidermoid or squamous-cell carcinoma is the designation for the type which shows stratification of the cells, intercellular bridges, wheel formation or keratinization (Kreyberg 1962, Spencer 1968)

The small-celled anaplastic carcinoma is characterized by small spheric to oval cells with very sparse cytoplasm. The cells are usually grouped in clusters or cords without stratification *Many mitoses are often seen* The basal, morphological criterion for the adenocarcinoma is the glandular structure with or without mucin.

The use of tobacco especially cigarette smoking, and other exogenous factors are important causal factors in the development of epidermoid carcinoma and small-celled anaplastic carcinoma, whereas the frequency of the adenocarcinoma is not *significantly* increased by excessive smoking (Liebow 1952 Kreyberg 1962)

Bronchogenic carcinoma rarely occurs be*fore the age of* 30–39 years, and its frequency increases steeply with advancing age

In most cases especially as far as squamous-cell and small-celled anaplastic carcinomata are *concerned, the surface epithelium seems* to be the site of origin of the tumour Presumably adenocarcinoma also arises from the surface epithelium (Jonas & Hukill 1968). Gradual transition from atypical stratified squamous epithelium to carcinoma in situ and manifest carcinoma may occur (Liebow 1952). It is usually assumed that most bronchogenic carcinomata arise from the epithelium covering the bronchi and bronchioles. Probably they develop from the basal cells, which are able to differentiate into cells which differ in function and structure (Walter & Pryce 1955 a).

Squamous-cell carcinoma arises from foci of squamous-cell metaplasia adenocarcinoma from atypical cylindrical cells or from mucous glands, while small-celled anaplastic carcinoma *is presumed to develop from basal cells of the* bronchial epithelium (Watson & Berg 1962 Spencer 1968)

One third of the squamous-cell carcinomata, three quarters of the adenocarcinomata and one fifth of the small-celled anaplastic carcinomata arise in the periphery of the bronchial system (Spencer 1968) Maamies (1966) found that of squamous-cell carcinomata 63 % were central, 22 % intermediate and 15 % peripheral The corresponding figures for adenocarcinomata were 44 % 30 % and 25 % and for small-celled anaplastic carcinoma 74 % *20 % and 6 % respectively In a group of re*sected tumours, Walter & Pryce (1955 b) found that squamous-cell carcinoma occurred more frequently centrally (44 %) than peripherally (28 %) while adenocarcinoma was most com*monly* localized peripherally (84 %) and that small-celled anaplastic carcinoma occurred

(Blumenfeld 1943 Johnson et al. 1960 Johnson et al. 1961). In certain normal tissues, for example, the intestinal epithelium, the mitotic activity is greater than in many tumours (Bertalanffy & Lau 1962 b)

However during carcinogenesis, the mitotic activity is often seen to increase from normal tissue through precancerous alterations to fully developed carcinoma (see page 56)

Whereas only a few cells with DNA values above the diploid value are revealed by photometric studies of normal tissues, many cells with a DNA content above that value will usually be found in cell populations of malignant tumour tissue (Atkin & Richards 1956, Sandritter, Müller et al. 1958). In various bronchogenic carcinomata, Sandritter Müller et al. (1958) thus found 50–90 % of the cell nuclei with DNA values higher than 1 /₂ × the modal value.

Numerous biochemical and microphotometrical studies of the DNA content of tumour tissue in animals and in man are on record, both in spontaneous, induced and transplanted tumours.

In biochemical studies, the average DNA value of the tumour-cell nuclei is determined by relating the DNA determinations to the number of tumour-cell nuclei. Of greater interest are microphotometric investigations, in which determination of the DNA content in individual nuclei can be performed in addition to measurements of the average DNA content of the tumour nuclei. In this way an expression of the distribution of the DNA values in the tumour tissue concerned is obtained. Good agreement between biochemical and microphotometric determinations of the average DNA value of cell nuclei was found by Leuchtenberger et al. (1952 a, 1952 b)

Microphotometric determinations of the DNA content has been performed in tumours from various human organs, especially the urogenital system, the skin and the mammary gland (Stowell & Cooper 1945 Stowell 1947 Sandritter 1952 a, 1952 b, Leuchtenberger et al. 1954 b, Atkin & Richards 1956, Grundmann et al. 1960 Atkin & Richards 1962, Sandritter & Fischer 1962, Laumonier et al. 1963 Atkin 1964 a, 1964 b Jacobsen 1968)

DNA Content of Bronchogenic Carcinomata

Microphotometric studies of bronchogenic carcinomata have mostly been sporadic investigations performed in connection with determination of the DNA content in tumours from various organs.

Among many other tumours, Stowell (1946) studied two bronchial adenocarcinomata. The average DNA content was 1.53 and 1 86 times, respectively as great as that of normal bronchial epithelial nuclei.

Among 19 carcinomata, Sandritter (1952 a) studied three squamous-cell carcinomata and five small-celled bronchial carcinomata (autopsy material). In terms of arbitrary units, the DNA content in squamous-cell carcinomata varied from 1 98 to 2.76, and the RNA content per cell, i. e. RNA in nucleus plus cytoplasm, from 1 43 to 1 8. In comparison, the small-celled bronchial carcinomata had DNA values within the range from 1.36 to 1.83 and a total RNA content per cell from 0 16 to 0.53

Leuchtenberger et al. (1954 b) studied a number of tumours, including two bronchial carcinomata, one anaplastic and one adenocarcinoma. In both tumours, the basal modal value was equal to the diploid value of the normal tissue, and a group of cell nuclei with the double value was also observed. In the adenocarcinoma, one cell with an octaploid value was found per 30 cells, while none with values above the tetraploid range among 28 nuclei were found in the anaplastic carcinoma.

Boriani & Gandolfi (1961) investigated the DNA content in various bronchial tumours. The results were stated in arbitrary units and compared with the content of the nuclei of normal bronchial epithelium, viz. 10 18 A. U The figures reported were: prickle-cell carcinoma, 52.85–104 67 A. U., polymorphous epithelioma, 59.55–73 92 A. U., microcytoma,

(1960) found a considerable decrease in the content of DNA and RNA in the parts of the tumour which showed grossly visible signs of necrosis. Even when visible necrosis was absent in the central part of a tumour the amounts of both DNA and RNA were reduced. However this loss was not as great as in tumours with grossly visible necrosis. Early necrosis may be demonstrated by a decrease in the DNA content. After ichaemia of the liver for 60–90 minutes, an irreversible reduction in the content of DNA in the cell nuclei occurred (James 1968)

Sandritter (1965) studied the content and the distribution of DNA in two tumours and found the same values peripherally and centrally in the cords of tumour cells.

Nuclear RNA

The nuclei of cancer cells will often appear dark and hyperchromatic, the hyperchromasia being a reflection of the ability of the nuclei—depending on the pH level—to bind basic stains

The calculation of the nuclear RNA content of cancer cells is very difficult. Most investigations of the nuclear RNA content have been made by biochemical methods. It is, however difficult to isolate the nucleus and determine the RNA content without contaminating it with cytoplasmic RNA and without loss of RNA

In microphotometry this determination is extremely difficult, as it will require measurements of the nucleic acid content in the nuclei without and with RNase treatment. On account of the very great dispersion of the nucleic acid content in the nuclei of cancer cells, a study of this character will have to comprise an enormous number of cell nuclei.

In chemical determinations and ultraviolet microphotometry Leuchtenberger et al (1952 a, 1952 b) found a content of RNA in tumour-cell nuclei of 20–25 % of the total nucleic acid content, as compared with only 3–7 % in normal cell nuclei.

It appears from a study of Goldberg et al (1950) that the chemically determined nuclear RNA content constituted about 16 % of the total nucleic acid content of the tumour-cell nucleus. In spontaneous leukaemia in mice, Peterman & Schneider (1951) found that the nuclear RNA was increased 1 6 times, while the nuclear RNA content in transplanted leukaemia was increased 4 2 times, as compared with normal It appears that the nuclear RNA in normal lymphocyte nuclei constituted about 4 3 % of the total nucleic acid content of the nuclei.

DNA Content of Malignant Tumours

The DNA content of normal cell nuclei is very constant, and shows only a slight variation on account of aneuploidity Variations in the DNA content are mainly due to DNA synthesis in preparation for mitosis

The DNA content in tumour tissue is characterized by a higher average level and by a wide dispersion of the values. The distribution curve for the DNA values in tumour tissues shows an accumulation of cells around a basal modal value which tends to be localized around the somatic diploid value (Koller 1960) or within the hyperdiploid range However it may also be found within the hypodiploid or tetraploid range. In addition, another peak is often seen at about twice the modal value. This is largely due to cells which have synthetized DNA in preparation for mitosis There are many intermediate values, which are due either to cells synthetizing DNA prior to mitosis, or to cells with an aneuploid DNA content (Bader 1959 Bader et al 1960) It is also characteristic of malignant tumours that DNA values above twice the modal DNA value are nearly always found

Increased mitotic activity is not presumed to be a contributory factor in carcinogenesis (Bader et al 1960) even though intense mitotic activity is often found in malignant tumours (Bertalanffy & Lau 1962 b)

In certain tumours, the mitotic activity is lower than in the corresponding normal tissue

It may occasionally be difficult to investigate the chromosomes in solid tumours as mitoses may either be rare or technically too bad for proper assessment (Makino et al. 1959)

An essential disadvantage of microphotometric investigations of the DNA content is that small numerical and structural aberrations of the chromosomes cannot be recorded. In chromosome studies, the number and morphology of the chromosomes can be accurately assessed when the material is suitable for this purpose (Hsu 1961).

Chromosomes in Tumour Tissue

Since the end of the last century an aetiological relationship between chromosome aberrations and malignancy has been assumed. Winge was the first to emphasize that tumour tissue consists of a population of heterogeneous cells, and that the origin and growth of a tumour are a selective process among the cells in this population (Levan 1956).

Mitotic irregularities are often seen in malignant tumour tissue, and malignant cells often contain an abnormal number of chromosomes (Levan 1956, Ising & Levan 1957) Whether these chromosome abnormalities are of primary significance, or secondary to the special environment in which they exist, is still a subject of discussion (Koller 1960) although most investigators are inclined to believe that they are primary (Hamerton 1961)

Chromosome investigations on experimentally induced ascitic tumours with demonstration of stem lines have shown that there is a certain degree of order in the chromosome conditions in tumour tissue. In each tumour there is a population of cells occurring with great frequency which has a characteristic chromosome pattern, and in which the behaviour of the chromosomes is absolutely regular during mitosis. These tumour cells contain a fixed modal number of chromosomes and form the stem line of the tumour (Makino 1957).

Such a cell type with a fixed modal number of chromosomes was demonstrated by Ford et al. (1958) in a number of tumours. The chromosomes in the tumour tissue differed both in number and morphology from those of normal cells. In all the tumours studied there was a certain variation in the number of chromosomes around the modal value, as distinct from the very slight variation in normal cell nuclei.

Variations in the chromosome number are due partly to a doubling of the chromosomes, either on account of errors in separation at anaphase or on account of doubling by endomitosis, and partly to a reduction in the chromosome number because of irregular multipolar spindles (Hauschka & Levan 1951), and to a continuous fluctuation around the modal value on account of disturbances at anaphase. These disturbances, which give rise to formation of aneuploid cells, probably occur with an appreciable frequency in tumour tissue. By scanning of Feulgen-stained sections of tumour nuclei at anaphase and telophase, Barka (1959) found that significant differences in the DNA content in the daughter cells occurred in three different tumours with a frequency of 41.5 % 16.7 % and 18 7 %

Chromosome studies are performed on cells at metaphase. These cells with a modal number of chromosomes are able to divide and are responsible for the growth of the tumour On the other hand, there are probably many other cells in tumour tissue which cannot be studied in this way as many aneuploid cells, in all probability are unable to synthetize DNA and form metaphases (Makino 1957 Hauschka 1963) It is possible that such aneuploid cells are not viable (Makino 1957 Stich & Steele 1962, Hauschka 1963 Stich 1963 Richards et al. 1956). Some are perhaps able to produce metaphases, but unable to complete the division (Bader 1959 Stich & Steele 1962)

In relation to the diploid value, which is found in normal cells of the organism, the stem line in tumours is most often situated within the hyperdiploid range, but may assume all values from hypodiploid through diploid and hyperdiploid to tetraploid or even higher Most commonly there will be one stem line, but

74 09–66 12 A U The average DNA content of all the tumours was thus considerably higher than that of the nuclei of normal bronchial epithelium.

Sandritter & Fischer (1962) studied the DNA content in a number of tumours including two small-celled bronchial carcinomata. Both had two peaks on the distribution curve one at the basal modal value within the hypodiploid and *the triploid range, respectively* and the second peak at the double value. In both cases, it appears from the distribution curve that there were also cell nuclei with values above the highest peak.

Sandritter & Kleinhans (1964) studied the dry weight, DNA content and histone content in eight different tumours, including five bronchial carcinomata, one small-celled and four squamous-cell carcinomata. The modal value *for the small-celled* carcinoma was within the hypodiploid range for the squamous-cell carcinomata it was within the diploid range yet with one exception within the hyperdiploid range. No relation was found between the *measurements* (the *distribution* pattern of DNA and the position of the stem line) on the one hand and the clinical course and histological structure on the other

The DNA content was studied microphoto*metrically in three squamous-cell carcinomata* by Sandritter Seidel et al (1965) The distribution curves show DNA values from diploid to hypertetraploid values in two cases, while the third case has a modal value within the tetraploid range with values extending into and even beyond the octaploid range

In ultraviolet absorption measurements on bronchial carcinomata, Hührer & Kaffenberger (1962) studied the nucleic acid content in two small-celled carcinomata one squamous-cell carcinoma and one adenocarcinoma. A great dispersion of the nucleic acid content was *found in* all the tumours, from the modal value up to the hypertetraploid range In one of the small-celled bronchial carcinomata, the average value was *of the same order as in the* normal cell nuclei but it appears from the figure that the modal value for this tumour was within the hypodiploid range.

In a study of scrapings from three bronchial squamous-cell carcinomata, Sandritter Müller et al *(1958)* found that *91 %, 50 %* and 73 % of the cells had a nucleic acid content exceeding $1^1/_2 \times$ the diploid value, and in one small-celled bronchial carcinoma 61 % of the cells had a DNA content above that value.

DNA Content—Chromosomes

Good agreement between microphotometric determinations of the DNA content in stem lines and the number of chromosomes was found by Leuchtenberger et al (1954 b), Klein (1955) Richards et al (1956) and Sandritter Hilwig et al (1965)

DNA determinations have certain adva tages over chromosome studies. *They are i* dependent of the structure of the tumou Both solid tumours and suspensions of canc cells may be used in such studies. The fr quency of mitoses is of no significance *connection with the measuring technique* Th material need not be freshly prepared and is easier to make a random selection of the t mours to be studied As contrasted with chr mosome studies, DNA determinations do n *require cells capable of forming* metaphase this is an advantage, as we cannot be su that all tumour-cell nuclei can do so (Makir 1957 Ising & Levan 1957) By means of micr photometry it is possible to study cells at stag of mitosis other than metaphase (Richards al 1956)

Finally microphotometric determinations a *probably the only way in which precancero* cells can be studied in the early stages c cancer as chromosome studies do not allo differentiation of tumour cells from norm cells, which will also divide (Hsu 1961) Photo metric investigations can be performed on his tological sections, which permits a definite mor phological identification of the cells in whicl *the nuclei* are to be studied (Emson & Kirl 1967)

in the tetraploid strain, these cells were less virulent, less invasive and required longer time to kill the animals than the more virulent diploid lymphomata (Hauschka et al. 1956)

Polyploid cells which developed by endomitosis without spindle formation were observed by Geitler (1939) in an insect. A few human organs will under normal conditions contain polyploid cell nuclei, viz. the liver and bone marrow (megakaryocytes) (Hauschka 1963). Furthermore, polyploid cells have been described in the pancreas and in testes in mice, and in various other organs in insects (Swift 1950)

In certain circumstances with hormonal overstimulation, polyploid cell nuclei may develop in non-neoplastic tissue. This applies, for example, to the endometrium (Wagner et al. 1968), the thyroid gland (Beierwaltes et al. 1966) the liver (Swartz 1956) the liver and pancreas (Leuchtenberger et al. 1954 a) Polyploid nuclei have also been observed in the urinary bladder (Walker 1958) and in muscle cells of hypertrophic human hearts (Kompmann et al. 1966)

According to the literature and my own investigations, polyploid nuclei are absent in normal bronchial epithelium.

The formation of polyploid nuclei may occur after the synthesis of DNA by an inhibition of mitosis, either by an inhibition of the duplication of the chromosomes or of their movements (Gelfant 1963)

Polyploidity is not necessarily a multiple of the euploid chromosome number as polyploidity represents all disturbances in the relation between the reproduction and the distribution of the chromosomes in the daughter cells (Levan & Hauschka 1953)

C-mitotic duplication, which resembles colchicine-induced mitotic inhibition, is due to failure in the kinetic apparatus.

Endomitosis involves a division of the contracted chromosomes inside the intact nuclear membrane, leading to endometaphase and back again to the despiralized stage. Orientation of the spindle is lacking, and the chromosomes are evenly distributed inside the nuclear membrane without formation of an equatorial plate of chromosomes at metaphase. The chromosomes are not arranged in pairs, and the daughter chromatids are unable to move from each other before the next mitosis.

In endoreduplication, a doubling of the chromosomes occurs in the despiralized stage inside the nuclear membrane without any mitosis-like manifestation. The chromosomes do not move from each other but persist as diplo-chromosomes until the next mitosis (Levan & Hauschka 1953) The high polyploid DNA content at interphase may reflect repeated endomitoses (Hauschka 1963)

Another mode of formation of polyploid nuclei was demonstrated by Robberts & Cole (1964) In ascitic tumour cells, polyploid cells could be formed from uninuclear cells with lower ploidity through an intermediate stage of binuclear cells. The binuclear cell was the result of lacking cytoplasmic cleavage in connection with the cell division. When the binuclear cell approached the next division, the chromosomes in both nuclei were united, and two uninuclear cells with a higher ploidity was found.

From numerous investigations of the DNA content and chromosomes in tumour tissue it appears, in the descriptions of cell distributions and in the histograms, that polyploid cell nuclei are found in many cases. However only a few indications of the frequency of these polyploid cell nuclei are available. Ishihara et al. (1963) found polyploid cell nuclei in pleural and ascitic fluids from cancer patients with a frequency of 10–40 % of the cell number At kin et al. (1959) studied the DNA content in a number of uterine carcinomata and found in a few tumours giant nuclei with values from 4 to 16 times the modal value. These cells occurred fairly often, but the frequency was not definitely stated. Koller (1956) mentioned that the frequency of polyploid, polynuclear degenerating and abnormally dividing cells in solid tumours is higher in differentiated than in anaplastic malignant tumours.

cases with two stem lines have also been reported.

When two stem lines exist they are usually situated very close to each other with a difference of only a few chromosomes Several of these tumours with two stem lines have been given radiotherapy or chemotherapy In two cases, modal chromosome numbers at a great distance from each other have been observed In both cases, the tumour had been subjected to radiotherapy and in both the highest peak was equal to twice the lower value (Hansen Melander et al 1956 Makino et al 1959 Ishihara et al 1963 Makino et al 1964 Atkin 1967) The cell group with the chromosome number at the double value was presumably produced from that with the low modal value. It is known that radiation therapy can produce doubling of the chromosome number by endomitosis and endoreduplication (Caspersson et al 1958 Richards & Atkin 1959 Bell & Baker 1962) and give rise to variations in the number and morphology of the chromosomes (Conger 1956 Upton 1963)

Polyploid Cell Nuclei

By polyploid cells is understood cells containing more than the diploid number of chromosomes (DeRobertis et al 1965) In analogy with this and with due allowance for premitotic DNA synthesis, polyploid cell nuclei may in microphotometry be defined as nuclei with a DNA content which is higher than twice the basal modal value.

As already mentioned in a population of cancer cells, there will be a certain variation in the number of chromosomes around the modal number of chromosomes of the tumour concerned This modal number of chromosomes is relatively constant in each tumour but genetic instability is a characteristic feature in cancer tissue and changes in the chromosomes may occur spontaneously without any explainable reason or during alterations in the growth conditions (Oberling & Bernhard 1961)

Levan & Biesele (1958) studied the cytological changes in embryonic tissue culture They demonstrated a gradually increasing number of polyploid cells at the expense of diploid cells. First a shift from diploidity to tetraploidity occurred, followed by a wider dispersion of the values above and below the tetraploid value and, finally by the formation of a heteroploid stem line with a chromosome number between the diploid and the tetraploid value A similar transformation was reported by Hsu & Klatt (1959)

In tissue cultures, substances may be formed which on accumulation affect the cells and may act as weak mitotic poisons. The rapid shift from diploid to tetraploid indicates either that tetraploid cells are more resistant to noxious substances than the diploid ones, resulting in a higher survival rate of the tetraploid cells, or that the diploid cells under the influence of a mitotic inhibitor in the medium are unable to undergo cytokinesis and therefore will become tetraploid (Hsu 1961)

Provided that the vital processes are preserved, a tetraploid cell is from a theoretical point of view only half as efficient as a diploid cell in mitosis. In order to divide once the former must synthetize twice as much material as the latter (Hsu 1961) This was shown experimentally by Hauschka et al (1957) in two ascitic tumours of identical genetic constitution. The hypertetraploid stem represented the duplication of the hyperdiploid stem and was isolated by selection from the hyperdiploid stem After transplantation, the number of cells was twice as large in the hyperdiploid as in the hypertetraploid stem after the first initial stage of growth, while the total tumour mass was equal in both tumours. The average generation time and mitotic time of the cells were twice as long in the hypertetraploid as in the hyperdiploid strain

In three mouse ascitic tumours isolated from the same highly virulent ascitic lymphosarcoma strain, the modal value of two of the tumours were near-diploid while one was tetraploid. In spite of a slight iso-antigenic effect of the cells

In the tetraploid strain, these cells were less virulent, less invasive and required longer time to kill the animals than the more virulent diploid lymphomata (Hauschka et al. 1956)

Polyploid cells which developed by endomitosis without spindle formation were observed by Geitler (1939) in an insect. A few human organs will under normal conditions contain polyploid cell nuclei, viz. the liver and bone marrow (megakaryocytes) (Hauschka 1963) Furthermore, polyploid cells have been described in the pancreas and in testes in mice, and in various other organs in insects (Swift 1950).

In certain circumstances with hormonal overstimulation, polyploid cell nuclei may develop in non-neoplastic tissue. This applies, for example, to the endometrium (Wagner et al. 1968), the thyroid gland (Beierwaltes et al. 1966) the liver (Swartz 1956) the liver and pancreas (Leuchtenberger et al. 1954 a) Polyploid nuclei have also been observed in the urinary bladder (Walker 1958) and in muscle cells of hypertrophic human hearts (Kompmann et al. 1966)

According to the literature and my own investigations, polyploid nuclei are absent in normal bronchial epithelium.

The formation of polyploid nuclei may occur after the synthesis of DNA by an inhibition of mitosis, either by an inhibition of the duplication of the chromosomes or of their movements (Gelfant 1963)

Polyploidity is not necessarily a multiple of the euploid chromosome number as polyploidity represents all disturbances in the relation between the reproduction and the distribution of the chromosomes in the daughter cells (Levan & Hauschka 1953)

C-mitotic duplication, which resembles colchicine-induced mitotic inhibition, is due to failure in the kinetic apparatus.

Levan & Biesele (1958) studied the cytological changes in embryonic tissue culture. They demonstrated a gradually increasing number of polyploid cells at the expense of diploid cells. First a shift from diploidity to tetraploidity occurred, followed by a wider dispersion of the values above and below the tetraploid value and finally by the formation of a heteroploid stem line with a chromosome number between the diploid and the tetraploid value A similar transformation was reported by Hsu & Klatt (1959)

In tissue cultures substances may be formed which, on accumulation, affect the cells and may act as weak mitotic poisons. The rapid shift from diploid to tetraploid indicates either that tetraploid cells are more resistant to noxious substances than the diploid ones, resulting in a higher survival rate of the tetraploid cells, or that the diploid cells under the influence of a mitotic inhibitor in the medium are unable to undergo cytokinesis and therefore will become tetraploid (Hsu 1961)

Provided that the vital processes are preserved, a tetraploid cell is from a theoretical point of view only half as efficient as a diploid cell in mitosis. In order to divide once the former must synthetize twice as much material as the latter (Hsu 1961) This was shown experimentally by Hauschka et al (1957) in two ascitic tumours of identical genetic constitution. The hypertetraploid stem represented the duplication of the hyperdiploid stem and was isolated by selection from the hyperdiploid stem After transplantation, the number of cells was twice as large in the hyperdiploid as in the hypertetraploid stem after the first initial stage of growth while the total tumour mass was equal in both tumours. The average generation time and mitotic time of the cells were twice as long in the hypertetraploid as in the hyperdiploid strain.

In three mouse ascitic tumours isolated from the same highly virulent ascitic lymphosarcoma strain the modal value of two of the tumours were near-diploid while one was tetraploid. In spite of a slight iso-antigenic effect of the cells

modal DNA value, the clinical stage, the age of the patient or the survival time, a significantly better prognosis was found in cervical carcinomata with modal values within the tetraploid range than in tumours with modal values within the diploid range (Atkin et al. 1962, Atkin 1964 a) The incidence of lymph-node metastases was significantly higher in the diploid class. The ploidity and the histological degree of differentiation were correlated in such a manner that most undifferentiated tumours had diploid stem lines, while the more differentiated tumours had predominantly tetraploid stem lines. The relationship between ploidity and prognosis was, however independent of that between ploidity and histological degree of malignancy

In chromosome studies of seven adenocarcinomata of the colon, Enterline et al. (1967) found that aggressive, poorly differentiated carcinomata had the lowest, near-diploid modal values, while the cells in the other carcinomata usually had higher numbers of chromosomes.

In 135 carcinomata of the prostate, Jacobsen (1968) found no correlation between the average nucleic acid content of the nuclei and the duration of symptoms to death or survival time after operation.

Studies of the chromosomes in various tumours failed to reveal a correlation between the degree of malignancy and that of structural changes in the chromosomes. Nor was any correlation observed between ploidity and the histological degree of differentiation of the tumour (Makino et al. 1959 Ishihara et al. 1963 Makino et al. 1964)

DNA Content of Metastases

In the literature, only a few studies of the DNA content of metastases are on record.

Leuchtenberger et al. (1954 b) reported that the dispersion of DNA values in metastases is wider than in the primary tumour

In a study of the DNA content in a case of malignant adenomatosis of the lung with metastases to the lymph nodes, Seidel & Sandritter (1963) found that the average DNA content in the metastatic tumour cells was only slightly higher than in the primary tumour The dispersion of the DNA content was also slightly higher The distribution pattern of the DNA values in the primary tumour was, however similar to that in the metastasis.

The mitotic frequency in the metastatic tumour cells corresponded to that in the tumour cells which proliferated in ascites. The cells which primarily participate in the formation of the metastatic tumour are probably stem cells, just as in the primary tumour (Makino 1957)

Chromosome studies on a metastasis from a carcinoma of the uterine cervix showed conditions similar to those observed in the primary tumour (Wakonig-Vaartaja et al. 1967).

By means of microphotometric measurements, Chu et al. (1961) determined the DNA content in five spontaneous and 11 metastatic mouse tumours. All metastatic tumours had a higher ploidity than the primary tumour

In a study of the DNA content in metastasizing primary bronchogenic carcinoma, Stich & Steele (1962) found a higher modal value in the primary tumour than in the metastasis.

Cytoplasmic RNA

In rapidly growing tissue, a high concentration of RNA is found in the cytoplasm. This applies, for example, to embryonic tissue and glands, in which intense protein synthesis occurs. RNA is a prerequisite for the production of protein in the cytoplasm, both during growth and in functional activity (Caspersson 1947)

In the carcinoma, type-A cells are characterized by a high concentration of protein and RNA in the cytoplasm, a large content of DNA in the nucleus, and well-developed nucleoli. This indicates a brisk activity of the protein-producing system in the cytoplasm and nucleus. Type-A cells are thus engaged in extremely intense growth and division, and the growth rate may be evaluated on the basis of the protein-producing system. The cytoplasm of type-B cells contains only a small amount

Chromosomes in Human Malignant Tumours

The chromosome constitution of 20 pleural and ascitic fluids from cancer patients was studied by Ishihara et al (1963) One of the tumours was a lung cancer (histological type not stated) The modal chromosome number was 101–102, i. e. within the hypertetraploid range. The wide dispersion of the chromosome number was a characteristic feature. There was no correlation between the degree of malignancy the modal number of chromosomes and structural changes in the chromosomes

In a case of anaplastic bronchogenic adenocarcinoma and one of gastric carcinoma the modal numbers of chromosomes were 75 and 82 respectively with a wide variation around the modal chromosome numbers. In both cases there was also a large number of cells with a considerably larger number of chromosomes, viz. 150 and 220 respectively These giant cells with the large number of chromosomes were presumed to have developed by endomitosis, because endometaphases occurred with a high frequency in both tumours (Ising & Levan 1957)

Makino et al. (1959) studied the chromosome constitution in 30 human tumours, including three squamous-cell bronchial carcinomata, which all had near-diploid stem lines. Incidentally the stem line was in most cases situated within the near-diploid or the hyper diploid range In some cases the stem line was near triploid and in a few it was hypotetraploid. A similar distribution of the stem lines was found in series of human tumours investigated by Makino et al (1964) but no correlation was demonstrated between the position of the stem line and the origin of the tumour or between the chromosome constitution and the histopathological structure of the tumour

In a series of 36 tumours of the female genital system, Wakonig Vaartaja et al (1967) found that the stem line might assume all values from hypodiploid to hypotetraploid In each type of tumour the number of cells with chromosome numbers within the near-diploid the near triploid and the near tetraploid range and within the range above this was stated.

In most human tumours, one particularly frequent cell type forming the stem cell of the tumour can be determined Most frequently there will be one stem line, but occasionally there may be two or even more. The stem lines from human tumours are usually localized within the near-diploid or the hyperdiploid range, but may vary from the hypodiploid to the tetraploid range. No relationship between the clinical course and the histopathological structure and chromosome pattern has been reported

DNA Content and Prognosis

Studying the average content of DNA and RNA in 14 squamous-cell carcinomata (including three bronchogenic) and in five small-celled carcinomata (all from the bronchi) Sandritter (1952 a) found that the cell division rate in normal cells and in tumour cells did not depend on the content of DNA and RNA It was concluded that the degree of malignancy in a tumour does not depend on the content of nucleic acids (Sandritter 1952 a 1952 b)

In a study of the DNA content in normal epithelium, in adenomatous polyps and in adenocarcinomata from the human colon, Stich et al (1960) failed to demonstrate any correlation between the degree of malignancy as assessed by histological examination and a certain aneuploid DNA content of the tumour cells.

In a number of tumours, including one small-celled bronchial carcinoma and four squamous cell bronchial carcinomata no correlation was demonstrated between the content and distribution pattern of DNA the position of the stem line and the clinical course and the histological structure of the tumour (Sandritter & Kleinhans 1964)

While Atkin et al (1959) in a study of the DNA content in carcinomata of the uterine cervix and corpus were unable to demonstrate a significant correlation between the basal

modal DNA value, the clinical stage, the age of the patient or the survival time, a significantly better prognosis was found in cervical carcinomata with modal values within the tetraploid range than in tumours with modal values within the diploid range (Atkin et al. 1962, Atkin 1964 a). The incidence of lymph-node metastases was significantly higher in the diploid class. The ploidity and the histological degree of differentiation were correlated in such a manner that most undifferentiated tumours had diploid stem lines, while the more differentiated tumours had predominantly tetraploid stem lines. The relationship between ploidity and prognosis was, however independent of that between ploidity and histological degree of malignancy

In chromosome studies of seven adenocarcinomata of the colon, Enterline et al. (1967) found that aggressive, poorly differentiated carcinomata had the lowest, near-diploid modal values, while the cells in the other carcinomata usually had higher numbers of chromosomes.

In 135 carcinomata of the prostate, Jacobsen (1968) found no correlation between the average nucleic acid content of the nuclei and the duration of symptoms to death or survival time after operation.

Studies of the chromosomes in various tumours failed to reveal a correlation between the degree of malignancy and that of structural changes in the chromosomes. Nor was any correlation observed between ploidity and the histological degree of differentiation of the tumour (Makino et al. 1959 Ishihara et al. 1963 Makino et al. 1964)

DNA Content of Metastases

In the literature, only a few studies of the DNA content of metastases are on record.

Leuchtenberger et al. (1954 b) reported that the dispersion of DNA values in metastases is wider than in the primary tumour

In a study of the DNA content in a case of malignant adenomatosis of the lung with metastases to the lymph nodes, Seidel & Sandritter (1963) found that the average DNA content in the metastatic tumour cells was only slightly higher than in the primary tumour The dispersion of the DNA content was also slightly higher The distribution pattern of the DNA values in the primary tumour was, however similar to that in the metastasis.

The mitotic frequency in the metastatic tumour cells corresponded to that in the tumour cells which proliferated in ascites. The cells which primarily participate in the formation of the metastatic tumour are probably stem cells, just as in the primary tumour (Makino 1957).

Chromosome studies on a metastasis from a carcinoma of the uterine cervix showed conditions similar to those observed in the primary tumour (Wakonig-Vaartaja et al. 1967)

By means of microphotometric measurements, Chu et al. (1961) determined the DNA content in five spontaneous and 11 metastatic mouse tumours. All metastatic tumours had a higher ploidity than the primary tumour

In a study of the DNA content in metastasizing primary bronchogenic carcinoma, Stich & Steele (1962) found a higher modal value in the primary tumour than in the metastasis.

Cytoplasmic RNA

In rapidly growing tissue, a high concentration of RNA is found in the cytoplasm. This applies, for example, to embryonic tissue and glands, in which intense protein synthesis occurs. RNA is a prerequisite for the production of protein in the cytoplasm, both during growth and in functional activity (Caspersson 1947)

In the carcinoma, type-A cells are characterized by a high concentration of protein and RNA in the cytoplasm, a large content of DNA in the nucleus, and well-developed nucleoli. This indicates a brisk activity of the protein-producing system in the cytoplasm and nucleus. Type-A cells are thus engaged in extremely intense growth and division, and the growth rate may be evaluated on the basis of the protein-producing system. The cytoplasm of type-B cells contains only a small amount

of protein and nearly no RNA They have large nuclei with only a small amount of nu cleic acids and very large nucleoli with a high *content of RNA Type B cells show a less in* tense growth activity with only slight protein synthesis (Caspersson & Santesson 1942)

The RNA content in tumour tissue was studied by Stowell (1946) The figures reported apply to the entire cell, i e cytoplasm plus nucleus. In many cases, there was no difference between the RNA content in tumour tissue and the corresponding normal tissue, but, in other cases, the tumour tissue revealed either a higher or a smaller RNA content than the normal tissue.

Cytophotometric investigations of gallo-cyanin-chromalum-stained tissue performed by Grundmann et al. (1960) showed that the epi thelial cytoplasm in the cervix of the uterus in precancerous stages contained more RNA than the normal epithelium

In a study of the RNA content of bronchogenic carcinomata, including three squamous-cell and five small-celled ones, Sandritter (1952 a) found that the RNA content of the small-celled bronchial carcinoma (stated for the entire cell i. e. nucleus plus cytoplasm) was considerably lower than that of the cells of the squamous-cell carcinoma. He mentioned that the small-celled bronchial carcinomata range among the most rapidly growing tu mours, and that they have a great propensity to metastasize. The high degree of malignancy with the high cell-division rate will provide little time for the construction of the protein forming system and thus Caspersson s theory as to cytoplasmic RNA was not confirmed as far as bronchogenic carcinomata were con cerned

Sandritter Müller et al (1958) studied the RNA concentration in sputum cells It was found to be considerably higher in the cytoplasm of squamous-cell bronchial carcinomata than in the ciliated cylindrical cells from the bronchial epithelium, but lower than in the cytoplasm of normal squamous cells from the oral mucosa.

Personal Investigations

The material studied consisted of biopsy specimens from 34 bronchogenic carcinomata, viz. squamous-cell carcinoma, 13 adenocarcinoma, 8 (two from the same patient, viz. B 11 and B 12) and small-celled anaplastic carcinoma, 13 (two from the same patient viz. N 5 and N 6)

The biopsy specimens are comparable as far as the localizations of the tumours are concerned all the biopsy specimens were removed by bronchoscopy and are thus from central tumours (see page 70)

None of the patients had been given radia tion therapy or been treated with cancer chemotherapeutic agents when the biopsy was performed

Nuclear Measurements

The nuclear measurements were all performed on RNase treated sections.

In each section 30–40 regular non-sec tioned nuclei selected at random, were subjected to measurements The values for the DNA content of the first 30 nuclei were used in the calculation of the average DNA content. The additional nuclei were measured in order to obtain a better evaluation of the position of the modal value.

Characteristic features of the DNA content in the bronchial carcinomata are as in other carcinomata the wide dispersion of the values and the high average content of DNA in the nuclei

The histograms in figure 38 show examples of the distribution of the DNA content in 30 nuclei from a squamous-cell carcinoma an adenocarcinoma and a small-celled anaplastic carcinoma.

After the calculation of the DNA content of the carcinoma nuclei the DNA values for each section were plotted in a histogram In this way it is possible with a reasonable de gree of certainty to assess the position of the modal value after measurements on 30–40 tu mour-cell nuclei (Atkin et al 1966)

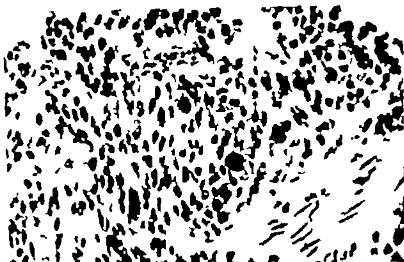

Fig. 35.—Squamous-cell carcinoma (gallocyanin-chromalum, × 350).

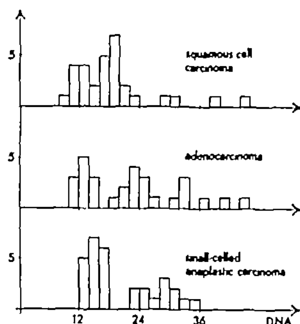

Fig. 38.—Distribution patterns of DNA content in squamous-cell carcinoma (section No E 26) adenocarcinoma (section No. B 6) and small-celled anaplastic carcinoma (section No. N 9)

Although no measurements were performed on sections showing necrosis, there may nevertheless be *measurable signs of this process* (see page 72) In order to assess this and to compare the DNA values for the various sections, the DNA content in each section was measured in cells with a normal *diploid* DNA content. Whenever possible the DNA content was therefore measured in normal epithelial nuclei when no epithelial tissue was available in the section it was measured in lymphocytes, which were nearly always present in the section. As appears from tables 35 36 and 37 there is some dispersion of the diploid values in the sections. This may be due partly to non visible, but measurable necrosis in the tissue and partly to technical or measuring errors in the sections.

In nearly all cases, the average DNA con-

tent in the tumour sections is considerably higher than that in the normal tissue. When corrected for measurable necroses and for technical and measuring errors by relating the average values of the tumours to a diploid value, fixed arbitrarily at 12.0 A. U., the values become comparable (listed as corrected DNA content in the tables). With the exception of a couple of the anaplastic carcinomata, the average DNA content was in all other cases considerably higher than the diploid value in the cell nuclei of the normal epithelium or in the lymphocytes. The average DNA content in all sections was higher in the squamous-cell and adenocarcinomata than in the small-celled anaplastic carcinoma.

The position of the modal value is stated in relation to diploid and near-diploid, triploid and near-triploid, tetraploid and near-tetraploid values. The limits were fixed so that the relation between the modal value and the diploid value in these ranges was 0.75–1.25, 1.25–1.75 and 1.75–2.25 respectively (Wakonig-Vaartaja et al. 1967) (table 38)

The distribution and position of the modal value in the various types of carcinoma appear from table 38. It is seen that there is no difference in the position of the modal value in the various groups, as about half of the tumours had a modal value within the diploid or near diploid range, while in the other half it was within the triploid or near-triploid range.

The modal value, as fixed by DNA determinations, will most often be an expression of one stem line, but as already mentioned, there may be more than one stem line. If so, they are most frequently situated very close to each other and will not to any considerable degree make the determination of the modal value by DNA measurements difficult. As none of the

patients had received radiotherapy there is no reason to assume the presence of stem lines at a long distance from each other (see page 76)

As the average DNA content was higher in the squamous-cell and adenocarcinomata than in the small-celled anaplastic carcinoma, it may be of interest to analyse the distribution of the DNA values in the various types of carcinoma.

The distribution of the DNA content in the tumour cell nuclei was determined The number of cell nuclei was stated around the modal value (up to the modal value + 2½ × the standard deviation with a coefficient of variation of about 10 % this is equal to the modal value + 2½ × the modal value 10 = 1¼ × the modal value) in the range from here up to twice the modal value (up to twice the modal value + 2½ × the standard deviation The standard deviation of the cells with a DNA content of twice the modal value was assumed to be twice the standard deviation of the cells with the modal value, i. e. up to 2 × the modal value + 2½ × 2 × the modal value 10 = 2½ × the modal value) and finally above the value (polyploid cell nuclei) (tables 39 40 41)

It appears from the tables that there is a considerably larger number of polyploid cell nuclei in the squamous-cell and adenocarcinomata than in the small-celled anaplastic carcinoma. In each section, however, only 30–40 tumour cell nuclei were measured. In order to study the number of polyploid cell nuclei in greater detail, measurements were performed in tumour sections on all nuclei which seemed to have a DNA content close to or above twice the modal value per 1500–2000 cell nuclei. These nuclei are very large and dark. If the

measured DNA content was higher than 2 ½ × the modal value, they were recorded as polyploid cell nuclei (figs. 39–47)

The number of polyploid cell nuclei in the various types of carcinoma is stated in tables 42, 43 and 44

The distribution of the number of polyploid cell nuclei per 1000 is represented graphically in figure 48.

It appears that the number of polyploid cell nuclei in the squamous-cell carcinoma and in the adenocarcinoma was 10 times as large as in the small-celled anaplastic carcinoma. (The numbers of polyploid cell nuclei in the two statements, viz. tables 39–41 and tables 42–44 differ because the DNA content in the former case is calculated from the content of only 30 nuclei, and the number is stated in relation to that of non-sectioned, regular nuclei, while the number in the latter case, in order to obtain more comparable values, is stated for a considerably larger number of cells (1500–2000) whether the nuclei were sectioned or not.)

In the polyploid cell nuclei of the small-celled anaplastic carcinoma the DNA concentration was relatively close to twice the modal value, whereas the squamous-cell carcinoma and adenocarcinoma contained many nuclei with a considerably increased content of DNA, up to 10–11 times as much as the basal modal value.

Table 45 shows the DNA content of the polyploid cell nuclei in relation to the modal value.

Metastases

The material studied consisted of 34 biopsy specimens of bronchogenic carcinomata from 32 patients who were all subjected to mediastinoscopy (Jepsen 1966) A positive specimen with carcinomatous tissue from the mediastinal lymph nodes was obtained in 12 patients (squamous-cell carcinoma, 3 adenocarcinoma, 5 and small-celled anaplastic carcinoma, 4) Carcinomatous tissue from the metastases suitable for microphotometric measurements was

have any significant influence on the cytoplasmic extinction (see table 47) Tables 46, 47 and 48 show the results of the cytoplasmic measurements in the various types of carcinoma.

It appears that the cytoplasmic extinction, as a reflection of the concentration of RNA in the squamous-cell carcinomata, is considerably higher in normal bronchial epithelium, and of the same order as in the metaplastic bronchial epithelium. With the aforementioned reservation, the same applies to the adenocarcinomata. In addition, the cytoplasmic volume in these two types of carcinoma must be estimated to be considerably larger than in the basal cells of normal bronchial epithelium. The total cytoplasmic content of RNA in the squamous-cell carcinomata, and also in the adenocarcinomata, thus seems to be considerably higher than in normal epithelium. In the small celled anaplastic carcinoma, the cell nucleus is surrounded only by a very thin rim of cytoplasm, which is apparently not thicker than that of the basal cells in the normal bronchial epithelium. As the concentration of cytoplasmic RNA in this type of carcinoma is a little lower than in the basal cells of normal epithelium, this means that the cytoplasmic RNA content is at least not greater than in the cytoplasm of the basal cells of normal bronchial epithelium, and is considerably less than that present in metaplastic epithelium as well as in the squamous-cell carcinoma and the adenocarcinoma.

Conclusions

Nuclear measurements in squamous-cell carcinomata, adenocarcinomata and small-celled anaplastic carcinomata revealed a considerably increased average content of DNA in the nuclei as compared with the nuclei in normal bronchial epithelium, with a wide dispersion of the values from the modal value up to twice that level and even higher

The corrected average value of the DNA content was lower in the small-celled anaplastic carcinoma than in the squamous-cell carcinoma and the adenocarcinoma. The relation, if any between the nucleic acid content in the bronchogenic carcinomata and the prognosis of these tumours thus seems to be that the most malignant type, the small-celled anaplastic carcinoma, on an average contains a smaller amount of DNA per *nucleus* than the less malignant squamous-cell carcinoma and adenocarcinoma.

The modal value of the tumour stem cells was within the diploid and near-diploid range or within the triploid and near-triploid range, without any difference between the various types of carcinomata.

Polyploid cell nuclei occurred with a considerably higher frequency in squamous-cell carcinoma and adenocarcinoma than in the highly malignant small-celled anaplastic carcinoma. This may mean that the two first mentioned tumour types provide less favourable growth conditions causing inhibition of mitosis, while the cells continue to synthetize DNA, resulting in the formation of large, dark nuclei with a high content of DNA.

The considerably greater malignancy of the small-celled anaplastic carcinoma is due to its greater tendency to rapid growth and rapid metastatic spread, and to its invasion of the

available only in one case (E 26). In this case, an average DNA content of the same order as in the primary tumour was found, and the distribution of the cell nuclei in the various classes and the number of polyploid cell nuclei were also as in the primary tumour (6.0 and 6.7 per thousand, respectively).

Of the 32 patients, three with squamous cell carcinoma and one with small-celled anaplastic carcinoma were alive after five years without signs of recurrence (the case of anaplastic carcinoma was accidentally revealed by *routine radiography*; *the tumour* was very small and produced no symptoms). The average survival times for the patients who died after the diagnosis had been made were for squamous cell carcinoma, adenocarcinoma and small celled anaplastic carcinoma 7.8 months, 3.9 months and 3.6 months, respectively.

A correlation between the number of polyploid cell nuclei in the carcinomata and the survival time of the patients cannot be established as the series is too small to allow any definite conclusions for that purpose.

Cytoplasmic Measurements

The average cytoplasmic extinction was determined in three areas in each tumour section. In each area, 50 measurements were performed with one or two measurements of the extinction on each tumour cell. In many sections of the adenocarcinomata, areas with PAS-positive mucin were present, giving a metachromatically red colour with gallocyanin-chromalum. In the measurements of the cytoplasmic extinction these areas with much PAS-positive material were avoided. It was, however, not possible in all cases completely to exclude absorption of metachromatically stained mucin in the adenocarcinomata. The measurements of the cytoplasmic extinction in this group of carcinomata must therefore be taken with some reservation.

The cytoplasmic measurements were all performed at the absorption maximum of nucleic acids, 570 nm. The absorption curve of the metachromatically stained mucin was determined in one RNase-treated gallocyanin-chromalum-stained section. The absorption maximum was found to be 540 nm, and at a wave length of 570 nm the absorption was only three quarters of that at the maximum. This contributes to a reduction in the cytoplasmic absorption of mucin at 570 nm. In one adenocarcinoma specimen (B 18) the tissue available was insufficient for cytoplasmic measurements on gallocyanin-chromalum stained sections.

RNase treatment had removed the cytoplasmic RNA from the sections, and only in the adenocarcinomata there remained a weak, metachromatically red colour which did not

SUMMARY

Chapter 1 gives a survey of the chemistry localization and function of nucleic acids. Histological methods for the demonstration of nucleic acids are discussed, and special mention is made of staining with gallocyanin-chromalum, including the theoretical background of the staining method. The advantages of this method in connection with photometric measurements are emphasized. The use of RNase in histological studies, especially of formalin-fixed tissue, is discussed. Furthermore, a survey is given of photometric investigations of histological sections, especially in visible light.

Chapter 2 contains a description of the series of bronchial biopsy specimens, fixation, RNase treatment and staining of the sections, and also of photometric measurements of the nuclear and cytoplasmic nucleic acid content of the epithelial tissue. The absorption curves for gallocyanin-chromalum in solution and bound to nucleic acids in bronchial epithelial nuclei were determined. It was shown that the absorption maxima were identical, whereas the curve for the tissue-bound gallocyanin-chromalum was at a higher level than that for gallocyanin-chromalum in solution, both within the long-wave and the short-wave range. The photometric measuring errors were determined in nuclei and cytoplasm.

Chapter 3 is concerned with the nucleic acid content in normal nuclei and the concentration of cytoplasmic RNA in various tissues.

In the basal cells of morphologically normal bronchial epithelium, the nucleic acid content was measured in nuclei and cytoplasm. No correlation was found between the nucleic acid content and the ages of the patients, diagnosis or smoking habits. No difference was revealed in the nucleic acid content of morphologically normal bronchial epithelium in a control group and in a group of patients with bronchogenic carcinoma elsewhere in the bronchial system.

The content of RNA of normal nuclei in the bronchial epithelium was calculated after measuring the nuclear nucleic acid content without and with RNase treatment. The nuclear RNA content was 1–6 % of the total nucleic acid content of the cell nucleus.

Methods for the determination of the mitotic activity are reviewed in *Chapter 4*. In the study of the nucleic acid content of bronchial epithelium a method was elaborated for the determination of the mitotic activity on the basis of photometric measurements of the DNA content of the cell nuclei. This method has proved to be suitable for relative determinations of the mitotic activity in bronchial epithelium.

On the basis of theoretical calculations of the distribution of DNA-synthetizing cells it was shown that the absolute number of mitoses in the bronchial epithelium can be estimated.

No difference was revealed in the mitotic activity of normal bronchial epithelium in a control group and in a group of patients with bronchogenic carcinoma elsewhere in the bronchial system. Correlated with the investigations in Chapter 3 this implies that in morphologically normal bronchial epithelium no difference can be demonstrated in the nucleic acid content in nuclei and cytoplasm, or in the mitotic activity in a control group and in a group of patients with bronchogenic carcinoma elsewhere in the bronchial system.

In *Chapter 5* the histological structure of the

pulmonary vessels. If the polyploid cells can be taken as a manifestation of unfavourable growth conditions and a lower malignancy it must be assumed that only relatively slight inhibition of the growth occurs in the small-celled anaplastic carcinoma as compared with the squamous-cell carcinoma and adenocarcinoma, which is in good agreement with clinical observations

The presence of polyploid cell nuclei in the bronchial epithelial tissue is nearly always suggestive of a malignant tumour since the only case with a polyploid cell nucleus without manifest malignancy was one of atypical metaplasia. On the other hand, the absence of polyploid cell nuclei does not exclude a malignant tumour because the small-celled anaplastic carcinoma contains only a few or no polyploid cell nuclei

Cytoplasmic measurements revealed a higher concentration and probably a higher content of cytoplasmic RNA in the squamous-cell and adenocarcinomata than in the basal cells of normal bronchial epithelium However the content of cytoplasmic RNA in the small-celled anaplastic carcinoma is probably of the same order as in the basal cells of normal epithelium, possibly lower

Thus the higher degree of malignancy of the small-celled anaplastic carcinoma is not reflected in a higher content of RNA in the cytoplasm.

SUMMARY

Chapter 1 gives a survey of the chemistry localization and function of nucleic acids. Histological methods for the demonstration of nucleic acids are discussed, and special mention is made of staining with gallocyanin-chromalum, including the theoretical background of the staining method. The advantages of this method in connection with photometric measurements are emphasized. The use of RNase in histological studies, especially of formalin-fixed tissue, is discussed. Furthermore, a survey is given of photometric investigations of histological sections, especially in visible light.

Chapter 2 contains a description of the series of bronchial biopsy specimens, fixation, RNase treatment and staining of the sections, and also of photometric measurements of the nuclear and cytoplasmic nucleic acid content of the epithelial tissue. The absorption curves for gallocyanin-chromalum in solution and bound to nucleic acids in bronchial epithelial nuclei were determined. It was shown that the absorption maxima were identical, whereas the curve for the tissue-bound gallocyanin-chromalum was at a higher level than that for gallocyanin-chromalum in solution, both within the long-wave and the short-wave range. The photometric measuring errors were determined in nuclei and cytoplasm.

Chapter 3 is concerned with the nucleic acid content in normal nuclei and the concentration of cytoplasmic RNA in various tissues.

In the basal cells of morphologically normal bronchial epithelium, the nucleic acid content was measured in nuclei and cytoplasm. No correlation was found between the nucleic acid content and the ages of the patients, diagnosis or smoking habits. No difference was revealed in the nucleic acid content of morphologically normal bronchial epithelium in a control group and in a group of patients with bronchogenic carcinoma elsewhere in the bronchial system.

The content of RNA of normal nuclei in the bronchial epithelium was calculated after measuring the nuclear nucleic acid content without and with RNase treatment. The nuclear RNA content was 1–6 % of the total nucleic acid content of the cell nucleus.

Methods for the determination of the mitotic activity are reviewed in *Chapter 4*. In the study of the nucleic acid content of bronchial epithelium a method was elaborated for the determination of the mitotic activity on the basis of photometric measurements of the DNA content of the cell nuclei. This method has proved to be suitable for relative determinations of the mitotic activity in bronchial epithelium.

On the basis of theoretical calculations of the distribution of DNA-synthetizing cells it was shown that the absolute number of mitoses in the bronchial epithelium can be estimated.

No difference was revealed in the mitotic activity of normal bronchial epithelium in a control group and in a group of patients with bronchogenic carcinoma elsewhere in the bronchial system. Correlated with the investigations in Chapter 3, this implies that in morphologically normal bronchial epithelium no difference can be demonstrated in the nucleic acid content in nuclei and cytoplasm, or in the mitotic activity in a control group and in a group of patients with bronchogenic carcinoma elsewhere in the bronchial system.

In *Chapter 5* the histological structure of the

pulmonary vessels. If the polyploid cells can be taken as a *manifestation of unfavourable* growth conditions and a lower malignancy it must be assumed that only relatively slight inhibition of the growth occurs in the small-celled anaplastic carcinoma as compared with the squamous-cell carcinoma and adenocarcinoma, which is in good agreement with clinical observations.

The presence of polyploid cell nuclei in the bronchial epithelial tissue is nearly always suggestive of a malignant tumour since the only case with a polyploid cell nucleus without manifest malignancy was one of atypical metaplasia. On the other hand, the absence of polyploid cell nuclei does not exclude a malignant tumour because the small-celled anaplastic carcinoma contains only a few or no polyploid cell nuclei.

Cytoplasmic measurements revealed a higher concentration and probably a higher content of cytoplasmic RNA in the squamous-cell and adenocarcinomata than in the basal cells of normal bronchial epithelium However the content of cytoplasmic RNA in the small-celled anaplastic carcinoma is probably of the same order as in the basal cells of normal epithelium, possibly lower

Thus the higher degree of malignancy of the small-celled anaplastic carcinoma is not reflected in a higher content of RNA in the cytoplasm.

RESUMÉ

I *kapitel 1* gives en oversigt over nucleinsyrernes kemi, lokalisation og funktion. Histologiske metoder til påvisning af nucleinsyrer diskuteres, og specielt omtales farvning med gallocyanin-chromalun og den teoretiske baggrund for farvemetoden. Dens fordele ved fotometriske målinger fremhæves. Anvendelsen af ribonuclease ved histologiske undersøgelser og især på formalinfixeret væv diskuteres. Endvidere gives en oversigt over fotometriske undersøgelser af histologiske præparater specielt i synligt lys.

I *kapitel 2* omtales materialet af bronchiebiopsier fixering, RNase behandling og farvning af materialet, og endvidere fotometriske målinger af nucleinsyreindholdet i kerner og cytoplasma i det epitheliale væv. Absorptionskurven for gallocyanin-chromalun i opløsning og bundet til nucleinsyre i bronchieepithelkerner blev bestemt. Det blev fundet, at absorptionsmaximum var det samme, medens kurven for det vævsbundne gallocyanin-chromalun lå højere end kurven for gallocyanin-chromalun i opløsning, både i det langbølgede og navnlig i det kortbølgede område. De fotometriske målefejl blev bestemt for bronchieepithelet i kerner og i cytoplasma.

I *kapitel 3* gives en oversigt over nucleinsyre indholdet i normale kerner og koncentrationen af cytoplasmatisk RNA i forskelligt væv.

I de basale celler i det morfologisk normale bronchieepithel blev nucleinsyreindholdet målt i kerner og i cytoplasma. Der blev ikke fundet nogen relation mellem nucleinsyreindhold og alder diagnose eller tobaksforbrug. Der blev ikke fundet nogen forskel mellem nucleinsyreindhold i morfologisk normalt bronchieepithel i en kontrolgruppe og i en patientgruppe med bronchogent carcinom et andet sted i bronchieepithelet.

Indholdet af RNA i normale kerner i bronchieepithelet blev beregnet efter måling af kernenucleinsyreindholdet uden og med RNase behandling. Kerne RNA indholdet var 1–6 % af kernens totale nucleinsyreindhold.

Metoder til bestemmelse af mitoseaktiviteten gennemgås i *kapitel 4*. Under undersøgelse af nucleinsyreindholdet i bronchieepithel, er der udarbejdet en metode til bestemmelse af mitoseaktiviteten på basis af fotometriske målinger af cellekernernes DNA indhold. Denne metode har vist sig velegnet til relative bestemmelser af mitoseaktiviteten i bronchieepithelet.

Efter teoretiske beregninger over fordelingen af DNA-synthetiserende celler kan det vises, at man til en vis grad også kan bedømme det absolutte antal mitoser i bronchieepithelet.

Der blev ikke fundet nogen forskel i mitoseaktiviteten i normalt bronchieepithel i en kontrolgruppe og i en patientgruppe med bronchogent carcinom et andet sted i bronchieepithelet. Sammenholdt med undersøgelserne i kapitel 3 vil det sige, at der ikke i morfologisk normalt bronchieepithel kan påvises nogen forskel i nucleinsyreindhold i kerner og i cytoplasma, eller i mitoseaktivitet hos en kontrolgruppe og en patientgruppe, som har udviklet bronchogent carcinom et andet sted i bronchieepithelet.

I *kapitel 5* beskrives det histologiske billede af metaplastiske forandringer i bronchieepithelet.

Ved forskellige grader af metaplasi blev der som udtryk for en forøget mitoseaktivitet, gennemsnitlig fundet et ca. 10 gange så stort antal hyperdiploide kerner som i det normale bron-

metaplastic alterations in the bronchial epithelium is described

In various degrees of metaplasia, the increased mitotic activity was reflected in an increase in the number of hyperdiploid nuclei, up to an average of about 10 times as many as in normal bronchial epithelium. In addition, an increased concentration of RNA in the cytoplasm was found Only when morphological changes such as metaplasia, occur in the bronchial epithelium can alterations in the nucleic acid content of the bronchial epithelium be disclosed, either in the form of an increased number of hyperdiploid nuclei or as an increased concentration of RNA in the cytoplasm.

In Chapter 6 a survey is given of the pathological anatomy of the bronchial adenoma and of the nucleic acid content and chromosome constitution in benign tumours The DNA content of the tumour stem line, the modal value was determined on the basis of the DNA content of normal epithelial nuclei or lymphocytes in the sections, and it was demonstrated that the modal value, apart from one exception within the triploid range, was within the diploid or near-diploid range. The number of hyperdi*ploid nuclei was three times as high as in nor*mal bronchial epithelium, while the cytoplasmic RNA concentration with a single exception, was as in the normal bronchial epithelium. Only in one case was the RNA concentration in the cytoplasm increased. Unlike the bronchogenic carcinomata, there was only a slight dispersion of the DNA content in the nuclei and unlike the carcinomata no values above twice the basal modal value were found

In Chapter 7 the classification of the bronchogenic carcinomata and factors responsible for the prognosis are mentioned. Furthermore a survey is given of *the DNA content and the* chromosomes of tumour cells The formation and the significance of the polyploid cell nuclei are discussed The measurements of the DNA content in bronchogenic carcinomata revealed a considerably increased average DNA content as compared *with normal nuclei, with a wide* dispersion of the values from the modal value up to twice that level and even higher

The average DNA content in tumour-cell nuclei was lower in the most malignant type, the small-celled anaplastic carcinoma than in the squamous-cell carcinoma and the adenocarcinoma.

No difference in the position of the modal value in the various types of carcinomata was found An analysis of the distribution of the *DNA values in bronchogenic tumours showed* that 10 times as many polyploid cell nuclei were present in squamous-cell and adenocarcinomata as in the small-celled anaplastic carcinoma. This suggests the existence of more unfavourable growth conditions in the first two tumours, resulting in inhibition of mitosis and formation of polyploid cell nuclei The occurrence of polyploid cell nuclei is nearly always suggestive of a malignant tumour On the other hand the absence of polyploid cell nuclei does *not exclude a bronchogenic carcinoma* because the small-celled anaplastic carcinoma contains only a few or no polyploid cell nuclei.

The cytoplasmic concentration of RNA was higher in the squamous-cell carcinoma and adenocarcinoma than in normal bronchial epithelium In the small-celled anaplastic carcinoma there is only a thin rim of cytoplasm around the nucleus with a low concentration of RNA While normal cells in intense growth or with a great activity contain a large amount of cytoplasmic RNA the high degree of malignancy in the small-celled anaplastic carcinoma is not reflected in a higher content of RNA in the cytoplasm

RESUME

I *kapitel 1* gives en oversigt over nucleinsyrer nes kemi, lokalisation og funktion. Histologiske metoder til påvisning af nucleinsyrer diskuteres, og specielt omtales farvning med gallocyanin-chromalun og den teoretiske baggrund for farvemetoden. Dens fordele ved fotometriske målinger fremhæves. Anvendelsen af ribonuclease ved histologiske undersøgelser og især på formalinfixeret væv diskuteres. Endvidere gives en oversigt over fotometriske undersøgelser af histologiske præparater specielt i synligt lys.

I *kapitel 2* omtales materialet af bronchiebiopsier fixering, RNase behandling og farvning af materialet, og endvidere fotometriske målinger af nucleinsyreindholdet i kerner og cytoplasma i det epithelale væv. Absorptionskurven for gallocyanin-chromalun i opløsning og bundet til nucleinsyre i bronchieepithelkerner blev bestemt. Det blev fundet, at absorptionsmaximum var det samme, medens kurven for det vævsbundne gallocyanin-chromalun lå højere end kurven for gallocyanin-chromalun i opløsning, både i det langbølgede og navnlig i det kortbølgede område. De fotometriske målefejl blev bestemt for bronchieepithelet i kerner og i cytoplasma.

I *kapitel 3* gives en oversigt over nucleinsyreindholdet i normale kerner og koncentrationen af cytoplasmatisk RNA i forskelligt væv.

I de basale celler i det morfologisk normale bronchieepithel blev nucleinsyreindholdet målt i kerner og i cytoplasma. Der blev ikke fundet nogen relation mellem nucleinsyreindhold og alder diagnose eller tobaksforbrug. Der blev ikke fundet nogen forskel mellem nucleinsyre indhold i morfologisk normalt bronchieepithel i en kontrolgruppe og i en patientgruppe med bronchogent carcinom et andet sted i bronchieepithelet.

Indholdet af RNA i normale kerner i bronchieepithelet blev beregnet efter måling af kernenucleinsyreindholdet uden og med RNase behandling. Kerne RNA indholdet var 1–6 % af kernens totale nucleinsyreindhold.

Metoder til bestemmelse af mitoseaktiviteten gennemgås i *kapitel 4*. Under undersøgelse af nucleinsyreindholdet i bronchieepithel, er der udarbejdet en metode til bestemmelse af mitoseaktiviteten på basis af fotometriske målinger af cellekernernes DNA indhold. Denne metode har vist sig velegnet til relative bestemmelser af mitoseaktiviteten i bronchieepithelet.

Efter teoretiske beregninger over fordelingen af DNA-syntetiserende celler kan det vises, at man til en vis grad også kan bedømme det absolutte antal mitoser i bronchieepithelet.

Der blev ikke fundet nogen forskel i mitose aktiviteten i normalt bronchieepithel i en kontrolgruppe og i en patientgruppe med bronchogent carcinom et andet sted i bronchieepithelet. Sammenholdt med undersøgelserne i kapitel 3 vil det sige, at der ikke i morfologisk normalt bronchieepithel kan påvises nogen forskel i nucleinsyreindhold i kerner og i cytoplasma, eller i mitoseaktivitet hos en kontrolgruppe og en patientgruppe, som har udviklet bronchogent carcinom et andet sted i bronchieepithelet.

I *kapitel 5* beskrives det histologiske billede af metaplastiske forandringer i bronchieepithelet.

Ved forskellige grader af metaplasi blev der som udtryk for en forøget mitoseaktivitet, gennemsnitlig fundet et ca. 10 gange så stort antal hyperdiploide kerner som i det normale bron-

metaplastic alterations in the bronchial epithelium is described.

In various degrees of metaplasia, the increased mitotic activity was reflected in an increase in the number of hyperdiploid nuclei, up to an average of about 10 times as many as in normal bronchial epithelium. In addition, an increased concentration of RNA in the cytoplasm was found. Only when morphological changes, such as metaplasia, occur in the bronchial epithelium can alterations in the nucleic acid content of the bronchial epithelium be disclosed either in the form of an increased number of hyperdiploid nuclei or as an increased concentration of RNA in the cytoplasm.

In *Chapter 6* a survey is given of the pathological anatomy of the bronchial adenoma and of the nucleic acid content and chromosome constitution in benign tumours The DNA content of the tumour stem line, the modal value was determined on the basis of the DNA content of normal epithelial nuclei or lymphocytes in the sections, and it was demonstrated that the modal value, apart from one exception within the triploid range, was within the diploid or near-diploid range The number of hyperdiploid nuclei was three times as high as in normal bronchial epithelium, while the cytoplasmic RNA concentration, with a single exception, was as in the normal bronchial epithelium. Only in one case was the RNA concentration in the cytoplasm increased Unlike the bronchogenic carcinomata, there was only a slight dispersion of the DNA content in the nuclei, and unlike the carcinomata no values above twice the basal modal value were found

In *Chapter 7* the classification of the bronchogenic carcinomata and factors responsible for the prognosis are mentioned. Furthermore, a survey is given of the DNA content and the chromosomes of tumour cells. The formation and the significance of the polyploid cell nuclei are discussed The measurements of the DNA content in bronchogenic carcinomata revealed a considerably increased average DNA content as compared with normal nuclei with a wide dispersion of the values from the modal value up to twice that level and even higher

The average DNA content in tumour-cell nuclei was lower in the most malignant type, the small-celled anaplastic carcinoma, than in the squamous-cell carcinoma and the adenocarcinoma

No difference in the position of the modal value in the various types of carcinomata was found An analysis of the distribution of the DNA values in bronchogenic tumours showed that 10 times as many polyploid cell nuclei were present in squamous-cell and adenocarcinomata as in the small-celled anaplastic carcinoma. This suggests the existence of more unfavourable growth conditions in the first two tumours, resulting in inhibition of mitosis and formation of polyploid cell nuclei The occurrence of polyploid cell nuclei is nearly always suggestive of a malignant tumour On the other hand, the absence of polyploid cell nuclei does not exclude a bronchogenic carcinoma, because the small-celled anaplastic carcinoma contains only a few or no polyploid cell nuclei

The cytoplasmic concentration of RNA was higher in the squamous-cell carcinoma and adenocarcinoma than in normal bronchial epithelium In the small-celled anaplastic carcinoma there is only a thin rim of cytoplasm around the nucleus with a low concentration of RNA While normal cells in intense growth or with a great activity contain a large amount of cytoplasmic RNA the high degree of malignancy in the small-celled anaplastic carcinoma is not reflected in a higher content of RNA in the cytoplasm.

chieepithel Endvidere blev der fundet en forøget koncentration af RNA i cytoplasmaet. Først når der optræder morfologiske ændringer i bronchieepithelet i form af metaplasi, kan der således påvises ændringer i bronchieepithelets nucleinsyreindhold, dels i form af et forøget antal hyperdiploide kerner dels i form af en forøget koncentration af RNA i cytoplasmaet.

I *kapitel 6* gives en oversigt over bronchial adenomets pathologiske anatomi og over nucleinsyreindhold og kromosomforhold i benigne tumorer DNA indholdet i tumorernes stamlinie, modalværdien, blev fastlagt på basis af DNA indholdet i normale epitheliale kerner eller i lymfocyter i præparaterne og det blev fundet, at modalværdien, med én undtagelse i det triploide område lå i det diploide eller nær-diploide område Antallet af hyperdiploide kerner var 3 gange så stort som i det normale bronchieepithel medens den cytoplasmatiske RNA koncentration med en enkelt undtagelse var som i det normale bronchieepithel. Kun i ét tilfælde var RNA koncentrationen i cytoplasmaet forhøjet. Til forskel fra de bronchogene carcinomer var der kun en ringe spredning i kernernes DNA indhold, og til forskel fra carcinomerne ingen værdier over det dobbelte af den basale modale værdi

I *kapitel 7* omtales klassificationen af de bronchogene carcinomer og de faktorer som har betydning for prognosen. Endvidere gives en oversigt over DNA indhold og kromosomer i tumorceller Dannelsen og betydningen af polyploide cellekerner omtales. Resultatet af målingerne af DNA indholdet i de bronchogene carcinomer viste et i forhold til normale kerner betydeligt forhøjet gennemsnitligt DNA indhold med en stor spredning af værdierne fra modalværdien til det dobbelte heraf og endnu højere

Den gennemsnitlige værdi af DNA indholdet i tumorcellekernerne var lavere i den mest maligne type, det småcellede anaplastiske carcinom, end i det planocellulære carcinom og adenocarcinomet.

Der blev ikke fundet nogen forskel i modalværdiens beliggenhed i de forskellige carcinomtyper Ved analyse af fordelingen af DNA værdierne i de bronchogene tumorer viste det sig, at der fandtes 10 gange så mange polyploide cellekerner i det planocellulære carcinom og i adenocarcinomet som i det småcellede anaplastiske carcinom. Det kan betyde, at der i de to førstnævnte tumorer er mere ugunstige vækstbetingelser som gør at mitoserne hæmmes, og at der dannes polyploide cellekerner Forekomsten af polyploide cellekerner i bronchieepithelet vil næsten altid betyde en malign tumor medens omvendt mangelen på polyploide cellekerner ikke udelukker et bronchogent carcinom, idet det småcellede anaplastiske carcinom kun indeholder få eller ingen polyploide cellekerner

Den cytoplasmatiske koncentration af RNA blev fundet højere i det planocellulære carcinom og i adenocarcinomet end i det normale bronchieepithel. I det småcellede anaplastiske carcinom er der kun en smal cytoplasmabræmme omkring kernen med en lav koncentration af RNA. Medens normale celler i intensiv vækst eller med stor aktivitet har et højt indhold af cytoplasmatisk RNA afspejler den høje malignitetsgrad af det småcellede anaplastiske carcinom sig således ikke i et højere indhold af RNA i cytoplasmaet.

CONTENTS

Abstract

Theories of hearing so far available cannot elucidate the numerous physical and medical observations regarding the hearing instrument. The main difficulty is presented by the cochlear partition which has been considered as one part, in spite of the fact that it consists of a great number of very precisely built and arranged parts. Therefore, detailed investigations were carried out on the ear of *Anoa buballs* which is very similar to that of man, and it was possible to obtain a clear and complete picture of the organ as a whole and of the function and interaction of its individual parts, and to develop a theory of hearing which explains numerous observations on hearing on a physical basis, and without requiring far-fetched arguments or obscure mechanisms.

The experiments permit representation of the cochlear partition as a cybernetic model of a highly involved frequency analysing instrument which may be briefly described as follows.

Oscillations of the endolymph are picked up by those narrow oblique segments of the tectorial membrane which possess corresponding natural frequencies. Due to the many oriented reinforcing fibrils the tectoria has anisotropic oscillator properties and its segments behave like the reeds of a reed-type frequency meter

The tectoria is connected to the stereocilia which bridge the gap to the reticular lamina. These transmitter pins act on the cuticular plate and this diaphragm piston displaces the cytoplasm of the transducers and strains the fine nerve endings at their lower side.

The transducers are mounted in a lattice girder The lower rigid plate of this girder (basilar membrane) supports the lower side of the transducers by means of the phalangeal cells, and the upper plate (reticular lamina) holds the upper rim of the transducers. These plates are connected by rows of pillars towards their center At the edges they are supported by border cells and cells of Hensen. The outer transducer rows are shifted relative to the preceding ones and this angle of shift corresponds to the oblique arrangement of the reinforcing fibers within the tectorial membrane This enhances the precision of the instrument. Tuning of first and of second order neurons and behaviour of synaptic connections improve the analysing properties of the described instrument further

The experiments established 132 essential dimensions of parts as function of the distance of the place of measurement from the stapes. In a detailed discussion it is shown that the theory is capable of explaining the essential phenomena of hearing.

Introduction

In spite of concerted research efforts of physicists, physiologists, histologists, biochemists, and ear nose, and throat experts for at least one-and-a-half centuries, the physical mode of functioning of the inner ear still remains practically unsolved.

Many theories have been proposed to account for the phenomena of hearing and have proliferated principally because the location of the inner ear makes *intra vita* observations difficult, and, due to the very small size of the various parts of the inner ear they are very difficult to measure, especially as they are rather susceptible to damage during experiments.

In view of the shortage of sufficient physical data on the inner ear and on the translation of mechanical processes into neural stimuli it is not surprising that one has sometimes even resorted to proposing obscure mechanisms to explain the hearing process.

This, however does not appear to be a desirable approach, but one should try to obtain a clear picture of the inner ear as a physical instrument. As until now the organ of Corti has been treated as one unit when considering its mode of action—in spite of its very complex design—and since only insufficient information was available on the performance and interaction of the individual parts of the organ of Corti and on the dimensional changes of the parts between the stapes and the helicotrema, it was decided to try to obtain such data by experiment. Such data would produce a detailed "workshop-drawing" of the inner ear which in turn would allow us to see whether the data obtained would be compatible with a working hypothesis on the functioning of the inner ear derived earlier by theoretical reasoning. At any rate, a complete physical picture of the inner ear was expected to result in a better understanding of the organ.

Before going into details of experiments and results a brief account of the structure of the ear is given for the benefit of the reader not specialized in this line, and because these lines contain some new observations.

Construction of the Ear System and its Working

The following description will of necessity be brief For a detailed account it is suggested to refer to papers mentioned in the text.

Dimensional data is compiled in Table I. The individual main parts of the ear system are shown in Fig. 1

(1) *The Outer Ear* Contrary to most mammalia the human pinna (cf. Fig. 1) has lost most of its movability It is generally believed that its purpose is to collect sound and to help to locate the direction of its source.

Observations in connection with this investigation show however that the pinna also serves to improve the sensitivity of the hearing system in a more general way For instance, if one rubs the ridge of the nose very gently with the tip of a finger normally no noise is perceived. If one puts on, however spectacles in such a way that the sides of their frame rest against the pinnae but do not touch the temporal bone, a repetition of the experiment produces a distinct noise. The vibrations caused by rubbing the finger tip on the ridge of the nose are transmitted by the sides of the frame to the pinnae. The pinnae are internally reinforced by cartilage, and this cartilage picks up the vibrations and passes them on to the hearing apparatus. A similar difference is found if one rubs gently the pinnae as compared to the temporal bone.

But sound waves, too, will cause vibrations of the pinnae, which are then transmitted on as tissue-conducted sound (Körperschall) Therefore, the pinnae will pick up all vibrations which reach them. The efficiency of the pinnae regarding improvement of sensitivity of the ear in general will depend on many factors. Firstly on their size because this will determine the area which is in a position to pick up sound energy from the oscillating air particles. Secondly movability will play a role in mammalian pinnae because it permits the animal to adjust the pinnae in such a way to the oncoming sound waves that a maximum area is exposed to the waves. Then rigidity of reinforcing cartilage will determine efficiency because, e.g. very soft ears (i.e. where the pinna is not equipped with strong internal cartilage), will not transmit the vibration onward to the inner ear as well as others which are well reinforced.

The shape of the outer ear is a further factor because the properly shaped auricle (as, e.g. in some species of bats) will act like an acoustic horn and funnel the sound energy into the external auditory meatus. Finally the direction of the sound waves impinging on the auricle will influence the efficiency in particular if the pinna is not movable, as in man.

It is felt, therefore, that the action of the mammalian pinnae goes beyond the simple sound wave collector action of a funnel.

It is known that the skull also picks up sound energy which is then transmitted onward to the inner ear However the pinnae are far more efficient for physical reasons, discussion of which is beyond the scope of this paper

From the pinna a tapering canal (external auditory meatus) of about 2.7 cm length leads to the drum (membrana tympani). This is a *conical membrane of about 0 1 mm thickness*, which is reinforced by many internal fibers. The external auditory meatus has a natural frequency of about 3 000 cps. The transmission characteristics of the external auditory meatus and of the membrana tympani have been extensively studied (1–21 et al) The pneumatic form of sound energy is transformed to mechanical energy at the drum.

(2) *Middle Ear* To the other side of the drum is attached the handle of the hammer (malleus). This hammer is connected to the anvil (incus), which in turn acts on the stirrup (stapes). As the handle of the hammer is longer

Item		Human ear[a]			*Anoa bubalis* (mean of 5 specimens)			Symbol (cf Fig. 4)	Remarks
		Min.	Average	Max.	Min.	Average	Max.		
Auditory meatus									
Cross section	(cm²)	0.3		0.5	0.37		0.8	*a* and *a*	Greater difference is due to greater length (horn effect)
Diameter	(cm)		0.7			1.0		*b*	No influence
Length	(cm)		2.7			7.0		*c*	Lower natural frequency of buffalo's external auditory meatus
Volume	(cm³)		1.0			4.1		*d*	No influence
Tympanic membrane									
Area	(cm²)	0.5		0.9	0.8		1.0	*e*	Less variation in area of buffalo's drums
Max. diameter	(mm)		ca. 10			ca. 12		*f*	The greater diameter corresponds to greater malleus length
Min. diameter	(mm)		ca. 8.5			ca. 8		*g*	
Thickness	(mm)		ca. 0.1			ca. 0.11		*h*	
Middle ear									
Malleus weight	(mg)		23			ca. 28		*i*	As malleus is suspended at center of gravity, therefore, no influence
Incus length	(mm)	5.5		6.0	6.6		7.8	*j*	Cf. remark under *f*
Incus weight	(mg)		27			ca. 76		*k*	Cf. remark under *i*
Stapes weight	(mg)		2.5			ca. 2.6		*l*	
length of footplate	(mm)		3.2			3.0		*m*	Footplate of buffalo more roundish than human one
width of footplate	(mm)		1.4			1.6		*n*	Cf. remark under *m*
area of footplate	(mm²)		3.2			3.4		*o*	Considering, *e*, *f* and *o*, overall transmission rather similar
Cochlea									
Length of cochlea duct	(mm)		35			36		*p*	Good agreement between ear of man and buffalo
Height of ducts	(mm)		ca. 1		0.4		1.2	*q*	No exact values for human ear. Influence negligible
Round window area	(mm²)		2			2.2			
Basilar membrane: width at stapes	(mm)		0.04			ca. 0.05		*s* }	Good agreement between width of basilar membrane and width ratio for man and *Anoa bubalis*
width at apex	(mm)		0.5			ca. 0.6		*t* }	
Helicotrema area	(mm²)	0.25		0.4	0.2		0.45	*u*	No influence
Max. diameter of coch.	(mm)		ca. 7		6.5		7.2	*v*	Good agreement
Height of cochlea	(mm)		ca. 6			ca. 6		*w*	Good agreement

[a] Data for human ear from refs. 25, 93–95.

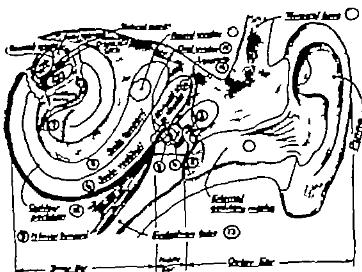

Fig. 1. Schematic diagram of human ear

(A) *Outer Ear*: Pinna
External auditory meatus (1)
Drum (membrana tympani) (2)

(B) *Middle Ear*
Hammer (Malleus) (3)
Anvil (Incus) (4)
Stirrup (Stapes) (5)
Eustachian tube (13)
Ligaments holding the ossicles (16)
Musculus tensor tympani (9)
Musculus stapedius (10)

(C) *Inner Ear*
Scala vestibuli (6)
Helicotrema (7)
Scala tympani (8)
Round window (11)
Oval window (15)
Cochlear partition (12)

The borders of the above sections of the ear have been indicated on the lower side of the drawing. The cochlear partition is shown once more in detail in the upper left corner. This represents a cross section through one semi turn of the cochlea. The three ducts (scala vestibuli, ductus cochlearis and scala tympani seperated by Reissner membrane and organ of Corti respectively) are clearly seen. The basilar membrane is on the lower side of the organ of Corti.

than the handle of the anvil (ratio ca. 1 : 1.3), the amplitudes of vibration are reduced. The footplate of the stapes is, furthermore, substantially smaller (ca. 3.2 mm²) than the active area of the drum (ca. 55 mm²). This leads to an increase of pressure at the footplate. This footplate is mounted into the oval window (fenestra ovalis) by means of an elastic ligament. It therefore moves like a piston, or as the movement is not exactly linear but somewhat rotational, rather like a flap. The footplate imparts the oscillations to the liquid (perilymph) in the scala vestibuli.

Malleus and Incus are attached to the walls of the cavity of the middle ear (cavum tympani) by ligaments, which are so arranged that these ossicles are suspended through their center of gravity, which enhances their transmission characteristics.

The middle ear ends at the footplate. Also the transmission characteristics of the middle ear are well known since long time (5, 19, 23–27 et al.)

The cavity of the middle ear is connected through the Eustachian tube to the rear part of the throat. This tube serves to keep pressure inside the middle ear equal to the outside pressure. To achieve this the Eustachian tube may be opened by tensioning certain muscles, e.g. the musculus tensor veli palatini, during the act of swallowing, or voluntarily.

To the handle of the hammer a muscle is

External auditory meatus (1)
Drum (membrana tympani) (2)

(B) *Middle Ear*
Hammer (Malleus) (3)
Anvil (Incus) (4)
Stirrup (Stapes) (5)
Eustachian tube (13)
Ligaments holding the ossicles (16)
Musculus tensor tympani (9)
Musculus stapedius (10)

(C) *Inner Ear*
Scala vestibuli (6)
Helicotrema (7)
Scala tympani (8)
Round window (11)
Oval window (15)
Cochlear partition (12)

The borders of the above sections of the ear have been indicated on the lower side of the drawing. The cochlear partition is shown once more in detail in the upper left corner. This represents a cross section through one semi turn of the cochlea. The three ducts (scala vestibuli, ductus cochlearis and scala tympani seperated by Reissner' membrane and organ of Corti respectively) are clearly seen. The basilar membrane is on the lower side of the organ of Corti.

than the handle of the anvil (ratio ca. 1 : 1.3), the amplitudes of vibration are reduced. The footplate of the stapes is, furthermore, substantially smaller (ca. 3.2 mm²) than the active area of the drum (ca. 55 mm²). This leads to an increase of pressure at the footplate. This footplate is mounted into the oval window (fenestra ovalis) by means of an elastic ligament. It therefore moves like a piston, or as the movement is not exactly linear but somewhat rotational, rather like a flap. The footplate imparts the oscillations to the liquid (perilymph) in the scala vestibuli.

Malleus and incus are attached to the walls of the cavity of the middle ear (cavum tympani) by ligaments, which are so arranged that these ossicles are suspended through their center of gravity which enhances their transmission characteristics.

The middle ear ends at the footplate. Also the transmission characteristics of the middle ear are well known since long time (5, 19, 23–27 et al.).

The cavity of the middle ear is connected through the Eustachian tube to the rear part of the throat. This tube serves to keep pressure inside the middle ear equal to the outside pressure. To achieve this the Eustachian tube may be opened by tensioning certain muscles, e.g. the musculus tensor veli palatini, during the act of swallowing, or voluntarily.

To the handle of the hammer a muscle is

For explanation of items, cf Fig. 5

connected (musculus tensor tympani) and another one (musculus stapedius) to the top of the stirrup The latter is the smallest muscle of the body Their effect has been studied extensively (10 28, 29 et al)

Békésy (23) has observed that the stapes may vibrate in two different modes If the ear is exposed to weak and medium sound intensity the footplate of the stapes rotates about a vertical axis which runs approximately perpendicular to the handle of the incus, and through the ligament which holds the footplate at the side of the other ossicles The footplate then acts like a flap as mentioned earlier

At elevated sound intensities the axis of rotation turns 90 and coincides with the longitudinal axis of the footplate. The volume of fluid pressed in and out of the scala is then reduced as the volume forced inwards on one side of the axis of rotation is compensated to a great extent by the volume escaping on the other side of the axis of rotation in the other direction. For this mechanism which protects the ear no explanation is found in literature

On the basis of the investigations carried out, the physical basis seems, however obvious. As the musculus stapedius contracts if the ear is exposed to an excessive sound, this will influence the mechanical behaviour of the system The tendon of the musculus stapedius runs parallel to the longitudinal axis through the footplate. Therefore a contraction of this muscle will reduce the degree of freedom of the oscillating footplate accordingly and a vibration about a new axis will result.

Whereas the drum is a form of energy converter (pneumatic into mechanical energy) the chain from the drum over the ossicles to the perilymph does not only transform mechanical to hydraulic energy but it also may be termed impedance converter matching the characteristics of the liquid in the inner ear to that of the air in the outer ear

(3) *Inner Ear* The inner ear comprises the extremely involved system of the cochlea which is so named due to its resemblance to

a snail shell. In terms of evolution it is the youngest part of the labyrinthine system, and is found in mammals only (30, 31).

Next to the cochlea in the labyrinth, or stato-acoustic organ, is the vestibular apparatus from which the cochlea has developed. This system responds to motion and position and does not concern us directly here.

The inner ear consists of a very complicated system of parts, many of which are minute (cf. Table II and Fig. 5). This part of the acoustic instrument has earned the reputation of being the most complicated organ of the human body.

As the exact design and performance of this part of the hearing instrument is the subject of discussion, a somewhat more detailed description will be appropriate.

The cochlea consists of the three ducts which are (i) the scala vestibuli, (ii) the scala tympani, and between these two (iii) the ductus cochlearis or scala media (cf. inset at upper left corner of Fig. 1 showing there a cross section of the ducts, and Fig. 5). Scala vestibuli and scala tympani are interconnected at the helicotrema at the apex of the cochlea, where the ductus cochlearis ends. Scala vestibuli and scala tympani are filled with perilymph, which is similar to extracellular fluid (K = 4.8 meq./liter, Na = 153.7 meq./liter, Cl = 120.5 meq./liter). The endolymph in the scala media is very similar to the electrolyte concentration of intracellular fluid (K = 137.7 meq./liter, Na = 15.2 meq./liter, Cl = 107.7 meq./liter (32)).

There is a steady d.c. potential in the scala media of about 50 to 100 mV, which is positive with respect to the scalae vestibuli and tympani. The tunnel and other spaces within the organ of Corti are filled with perilymph (32). Some authors call it cortilymph (33). Reissner's membrane and the membrana reticularis are impermeable to sodium and potassium ions, the basilar membrane is, however, permeable. The potential difference from cells of the organ of Corti to the perilymph is 80 to 130 mV. This d.c. potential, however, is not the source of the cochlear microphonic which is discussed later, according to recent studies (34, et al.). The fact that the spaces in the organ of Corti are filled with perilymph, enables the un-myelinated nerve fibers crossing them, to conduct impulses (32, 35).

The scala tympani and the scala vestibuli are partly separated by a bony shelf (lamina spiralis ossea). The gap between this lamina and the spiral ligament is bridged by the basilar membrane. As the distance between the lamina spiralis ossea and the spiral ligament grows from the base of the cochlea, i.e. near to the stapes, to the apex at the helicotrema, the width of the basilar membrane grows progressively too. The basilar membrane is reinforced internally by many fibers. Békésy (36) has reported isotropic mechanical properties, Iurato (37) found anisotropic structure with most fibers running transversely.

The bony shelf carries the limbus spiralis, at the upper side of which are the teeth of Huschke (cf. Fig. 4). There are about 7 000 of them along the cochlear partition. To their upper side the membrana tectoria is attached. This membrane is internally reinforced by many fine fibrils (38–40), which run practically parallel to each other, and at an angle of about 20 to the transversal direction of the cochlear partition (cf. Fig. 2). There is practically no longitudinal interlacing of these reinforcing fibers. These fibers can be clearly seen in Figs. 7 and 9. Due to this internal reinforcement the tectorial membrane possesses considerable anisotropic mechanical properties.

The lower side of the basilar membrane carries a layer of connective tissue and a spiral blood vessel, the upper side carries the organ of Corti.

The organ of Corti (cf. Fig. 5) consists of a row of inner and a row of outer pillars which are placed on the basilar membrane at some distance from each other. The rows of pillars meet at their top. They are internally reinforced by fibers. At their top the reticular lamina is attached, which is also reinforced

connected (musculus tensor tympani) and an other one (musculus stapedius) to the top of the stirrup The latter is the smallest muscle of the body Their effect has been studied ex tensively (10 28 29 et al)

Békésy (23) has observed that the stapes may vibrate in two different modes If the ear is exposed to weak and medium sound intensity the footplate of the stapes rotates about a vertical axis which runs approximately per pendicular to the handle of the incus, and through the ligament which holds the footplate at the side of the other ossicles. The footplate then acts like a flap as mentioned earlier

At elevated sound intensities the axis of rotation turns 90 and coincides with the longitudinal axis of the footplate. The volume of fluid pressed in and out of the scala is then reduced as the volume forced inwards on one side of the axis of rotation is compensated to a great extent by the volume escaping on the other side of the axis of rotation in the other direction. For this mechanism which protects the ear no explanation is found in literature

On the basis of the investigations carried out, the physical basis seems, however obvious As the musculus stapedius contracts if the ear is exposed to an excessive sound this will influence the mechanical behaviour of the system The tendon of the musculus stapedius runs parallel to the longitudinal axis through the footplate Therefore, a contraction of this muscle will reduce the degree of freedom of the oscillating footplate accordingly and a vibration about a new axis will result.

Whereas the drum is a form of energy converter (pneumatic into mechanical energy) the chain from the drum over the ossicles to the perilymph does not only transform mechanical to hydraulic energy but it also may be termed impedance converter matching the characteristics of the liquid in the inner ear to that of the air in the outer ear

(3) *Inner Ear* The inner ear comprises the extremely involved system of the cochlea, which is so named due to its resemblance to

a small shell. In terms of evolution it is the youngest part of the labyrinthine system, and is found in mammalia only (30 31).

Next to the cochlea in the labyrinth, or stato-acoustic organ, is the vestibular apparatus from which the cochlea has developed. This system responds to motion and position and does not concern us directly here.

The inner ear consists of a very complicated system of parts, many of which are minute (cf. Table II and Fig. 5) This part of the acoustic instrument has earned the reputation of being the most complicated organ of the human body

As the exact design and performance of this part of the hearing instrument is the subject of discussion, a somewhat more detailed description will be appropriate.

The cochlea consists of the three ducts which are (i) the scala vestibuli, (ii) the scala tympani, and between these two (iii) the ductus cochlearis or scala media (cf inset at upper left corner of Fig. 1 showing there a cross section of the ducts, and Fig. 5). Scala vestibuli and scala tympani are interconnected at the helicotrema at the apex of the cochlea, where the ductus cochlearis ends. Scala vestibuli and scala tympani are filled with perilymph, which is similar to extracellular fluid (K ~4 8 meq / liter Na ~153 7 meq /liter Cl ~120.5 meq /liter). The endolymph in the scala media is very similar to the electrolyte concentration of intracellular fluid (K ~137 7 meq /liter Na ~15.2 meq /liter Cl ~107 7 meq /liter (3)).

There is a steady d c. potential in the scala media of about 50 to 100 mV which is positive with respect to the scalae vestibuli and tympani. The tunnel and other spaces within the organ of Corti are filled with perilymph (32). Some authors call it cortilymph (33) Reissner's membrane and the membrana reticularis are impermeable to sodium and potassium ions the *basilar* membrane is, however permeable. The potential difference from cells of the organ of Corti to the perilymph is 80 to 130 mV This d c. potential, however is not the source of the cochlear microphonic which is discussed later according to recent studies (34 et al.). The fact that the spaces in the organ of Corti are filled with perilymph, enables the un-myelinated nerve fibers crossing them, to conduct impulses (32, 35)

The scala tympani and the scala vestibuli are partly separated by a bony shelf (lamina spiralis ossea). The gap between this lamina and the spiral ligament is bridged by the basilar membrane As the distance between the lamina spiralis ossea and the spiral ligament grows from the base of the cochlea, i.e. near to the stapes, to the apex at the helicotrema, the width of the basilar membrane grows progressively too The basilar membrane is reinforced internally by many fibers. Békésy (36) has reported isotropic mechanical properties, Iurato (37) found anisotropic structure with most fibers running transversely

The bony shelf carries the limbus *spiralis*, at the upper side of which are the teeth of Huschke (cf. Fig. 2). There are about 7 000 of them along the cochlear partition. To their upper side the membrana tectoria is attached. This membrane is internally reinforced by many fine fibrils (38–40) which run practically parallel to each other and at an angle of about 20 to the transversal direction of the cochlear partition (cf. Fig. 2) There is practically no longitudinal interlacing of these reinforcing fibers. These fibers can be clearly seen in Figs. 7 and 9 Due to this internal reinforcement the tectorial membrane possesses considerable anisotropic mechanical properties.

The lower side of the basilar membrane carries a layer of connective tissue and a spiral blood vessel, the upper side carries the organ of Corti.

The organ of Corti (cf. Fig. 5) consists of a row of inner and a row of outer pillars which are placed on the basilar membrane at some distance from each other The rows of pillars meet at their top They are internally reinforced by fibers. At their top the reticular lamina is attached, which is also reinforced

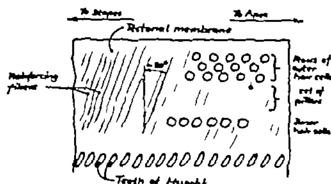

Fig 2 Top view (so-called surface preparation) of the tectorial membrane. The rows of the outer hair cells and the inner row can be seen. Further the *feet of the rows of outer and of inner pillars* have been shown in this schematic drawing. The angle of the reinforcing fibers in the tectorial membrane is about 20° In the bottom of the illustration the row of teeth of Huschke is shown. The tectorial membrane is attached to the top of these teeth.

a strong platelike structure. The inner rim of the reticular lamina is attached to the border cells, which in turn rest on the basilar membrane the outer edge is connected to the cells of Hensen which also rest on the basilar membrane

In the inner portion of the reticular lamina is mounted a row of hair cells (transducers) i.e. the upper rim of the transducers is attached to the reticular lamina The lower side of each transducer rests on a phalangeal cell, which is internally reinforced by fibers The phalangeal cells are placed on the basilar membrane.

The top of the transducer is closed by a cuticular plate This cuticular plate carries a set of hairs due to which these cells are called hair cells

The outer portion of the reticular lamina carries normally *three rows of outer hair cells,* the design and mounting of which corresponds *to that of the* inner hair cells There are about 3 500 inner and about 20 000 outer hair cells. The outer rows of hair cells are off set against each other (cf Fig 2) in a very regular way as may be seen in surface preparations of the organ of Corti (41 42 et al) Whether the hair cells are connected to the tectorial membrane or not is still disputed (41–44 et al)

According to present views (45–53) nerve fibers terminate in tulip-like endings at the *lower portion of the inner hair cells* The outer hair cells show three types of nerve endings, again arranged *at the lower portion of the hair* cells.

The efferent *nerve fiber bundle contains* about 500 fibers. There are further about *25 000 afferent fibers (45) The efferent fibers* are mostly collected in bundles, like in a switchboard at the spiral tunnel bundle *from* where they reach the outer hair cells, and again at the inner spiral bundle from where they pass between the foot plates of the inner row of pillars (rods of Corti) to join the spiral tunnel bundle (38 54) From the transducers across the tunnel and along the bundles until the fibers reach the habenula perforata, the nerve fibers are not myelinated At the latter place, i.e at the outer edge of the bony shelf the myelin sheet starts and covers the nerves on their further path

A little further on, the nerve fibers reach the spiral ganglion which contains about 25 000 bipolar cells. No synaptic connections are recognized there. The cell bodies in this long spiral ganglion are more densely grouped towards the base (900 to 1 100 per mm) than towards the apex (about 500 per mm) The transition is gradual (55)

From the spiral ganglion the auditory nerve leaves the cochlea through the modiolus (internal auditory meatus) (cf Fig 3) The fibers in the auditory nerve are *arranged in an orderly* way and twist like the strands of a rope.

A *detailed description of the inner* ear may be obtained from the references referred to in *this chapter* and later on. The physical properties of the inner ear will be described when discussing the cybernetic model of the theory of hearing proposed later on

(4) *Auditory Pathway and Cortex* Although the higher neural pathways and the auditory cortex do not belong to the ear system within the scope of this paper a brief description will be given as reference is made to it later on.

A schematic

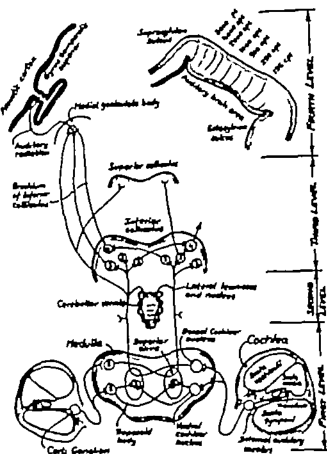

Fig. 3. General arrangement of the auditory pathway between the cochlea and the auditory cortex of the brain. On the right the different levels have been shown. Further more numbers from 1 to 4 inserted inside the synapses show the order of neurons.

From the second level onwards only the connections to the left hemisphere of the brain have been shown, whereas in the upper right corner the distribution of frequencies on the auditory brain area is indicated.

Attention is drawn to the cross connections between both ears and both brain hemispheres at the medulla and at the inferior colliculus. The pathways have been shown in very simplified way to maintain lucidity

tory pathways and of the auditory cortex are shown in Fig. 3

This system may be divided into a first level which comprises the nuclei in the lower brain stem (superior olive trapezoid body and lateral lemniscus), the second level which covers the cerebellum, the third one with the inferior colliculus at the upper pontine level and finally the fourth level from the medial geniculate body to the cortex.

The order of the neurons has been indicated in Fig. 3 according to the mostly adopted system (56).

It is seen that both sides are interconnected at various levels, which is important when considering certain observations on hearing. It is also seen that the frequencies are arranged in an orderly way on the cortex (57) however such evaluations have practically exclusively been done on animals cortex. There is, however no reason why the human cortex should not be arranged in a similar way

Regarding the electrical phenomena of the hearing instrument and of higher centers, one will have to start with the aural or cochlear microphonics. If electrodes are placed on the round window and at some place of head or neck tissue, an electrical potential is observed which is generated within the cochlea and which represents the sound pressure change of an acoustic stimulus very well. This electric potential remains nearly proportional to the

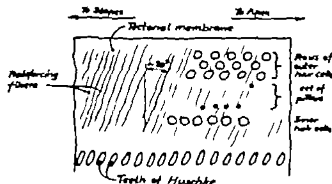

Fig 2 Top view (so-called surface preparation) of the tectorial membrane. The rows of the outer hair cells and the inner row can be seen. a strong platelike structure The inner rim of the reticular lamina is attached to the border cells, *which in turn rest on the basilar mem* brane, the outer edge is connected to the cells of Hensen which also rest on the basilar mem brane

In the inner portion of the reticular lamina is mounted a row of hair cells (transducers) i.e. the upper rim of the transducers is at tached to the reticular lamina. The lower side of each transducer rests on a phalangeal cell, *which is internally reinforced by fibers. The* phalangeal cells are placed on the basilar mem brane.

The top of the transducer is closed by a cuticular plate This cuticular plate carries a set of hairs, due to which these cells are called hair cells

The outer portion of the reticular lamina carries normally three rows of outer hair cells, the design and mounting of which corresponds to that of the inner hair cells There are about 3 500 inner and about 20 000 outer hair cells. The outer rows of hair cells are off-set against *each other (cf Fig 2)* in a very regular way as may be seen in surface preparations of the organ *of Corti (41 42, et al)* Whether the hair cells are connected to the tectorial mem brane or not is still disputed (41–44 et al)

According to present views (45–53) nerve fibers terminate in tulip-like endings at the lower *portion of the inner hair cells. The* outer hair cells show three types of nerve endings, again arranged at the lower portion of the hair cells.

The efferent nerve fiber bundle contains about 500 fibers. There are further about 25 000 afferent fibers (45) The efferent fibers are mostly collected in bundles, like in a switchboard at the spiral tunnel bundle from *where they reach the outer hair cells, and again* at the inner spiral bundle from where they pass between the foot plates of the inner row of pillars (rods of Corti) to join the spiral tunnel bundle (38 54) From the transducers across the tunnel and along the bundles until the fibers reach the habenula perforata, the nerve fibers are not myelinated At the latter place, i e at the outer edge of the bony shelf *the myelin sheet starts and covers* the nerves on their further path

A little further on the nerve fibers reach the spiral ganglion which contains about 25 000 bipolar cells. No synaptic connections are recognized there The cell bodies in this long spiral ganglion are more densely grouped towards the base (900 to 1 100 per mm) than towards the apex (about 500 per mm) The *transition is gradual (55)*

From the spiral ganglion the auditory nerve *leaves the cochlea through the modiolus* (in ternal auditory meatus) (cf Fig. 3) The fibers in the auditory nerve are arranged in an or derly way and twist like the strands of a rope.

A detailed description of the inner ear may be obtained from the references referred to in this chapter and later on The physical prop erties of the inner ear will be described when discussing the cybernetic model of the theory of hearing proposed later on.

(4) *Auditory Pathway and Cortex Al though the higher* neural pathways and the auditory cortex do not belong to the ear system within the scope of this paper a brief descrip tion will be given as reference is made to it *later on*

A schematic arrangement of the neural audi

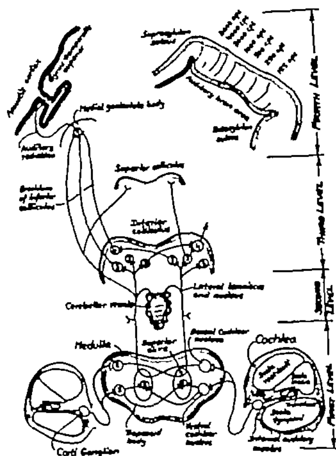

Fig 3 General arrangement of the uditory pathway between the cochlea and the auditory cortex of the brain. On the right the different levels have been shown. Furthermore numbers from 1 to 4 inserted inside the synapses show the order of neurons.

From the second level onw rds only the connections to the left hemisphere of the brain have been shown, whereas in the upper right corner the distribution of frequencies on the uditory brain area is indicated.

Attention is drawn to the cross connections between both ears and both brain hemispheres at the me dulla and at the inferior colliculus. The pathways have been shown in very simplified way to maintain lucidity

tory pathways and of the auditory cortex are shown in Fig. 3

This system may be divided into a first level which comprises the nuclei in the lower brain stem (superior olive, trapezoid body and lateral lemniscus), the second level which covers the cerebellum the third one with the inferior colliculus at the upper pontine level, and finally the fourth level from the medial geniculate body to the cortex.

The order of the neurons has been indicated in Fig. 3 according to the mostly adopted system (56)

It is seen that both sides are interconnected at various levels, which is important when considering certain observations on hearing. It is also seen that the frequencies are arranged in an orderly way on the cortex (57), however such evaluations have practically exclusively been done on animals cortex. There is, however no reason why the human cortex should not be arranged in a similar way

Regarding the electrical phenomena of the hearing instrument and of higher centers, one will have to start with the aural or cochlear microphonics. If electrodes are placed on the round window and at some place of head or neck tissue, an electrical potential is observed which is generated within the cochlea and which represents the sound pressure change of an acoustic stimulus very well. This electric potential remains nearly proportional to the

sound pressure over a considerable pressure range (27) It also appears due to a bone con ducted sound if drum, malleus, and incus have been removed surgically and after degeneration of the auditory nerve upon transsection at the internal auditory meatus

The polarity of the cochlear microphonic at the round window is opposite that at the oval window as if the generator would be located on and perpendicular to the cochlear partition. The origin of the cochlear microphonic is still uncertain and has been attributed nearly to any structure within the cochlea (27 et al.) How ever the fact that congenitally deaf animals which have no organ of Corti but a normal basilar membrane and Reissner's membrane, produce no cochlear microphonics, indicate that the generators may be located within the organ of Corti This, and the polarity accounts for the generally accepted hypothesis to attri *bute the cochlear microphonic to the hair cells* (transducers)

The electrical potential in the eight nerve (auditory nerve) follows the stimulating frequency only up to about 1 200 cps The reason *is that the activity of each of the about 30 000* nerve fibers in the auditory nerve follows the all-or none character of nerve action potentials (58–60) This means that a stimulus above a certain threshold will trigger an action poten tial of relatively constant amplitude (disregarding, e g. reduced amplitudes for repetitive re sponse (60), or if the frequency is such that each subsequent action potential falls into the latter part of the refractory period (59)) The all-or none rule is to a certain extent a misnomer because stimuli below threshold cause effects at synaptic connections (e g. facilitation) and at ganglions As synapses are *normally* served by several connections, the number as well as the intensity and/or time pattern of the in-coming signals is of importance (61–63) Synaptic connections work like one-way valves, *transmitting stimuli only* in one direction

The absolute refractory period, during which no second action potential can be induced, determines a certain *maximum* frequency of the action potentials in a nerve fiber which cannot be exceeded. Therefore, at higher acoustic frequencies *the individual nerve fiber* cannot respond to every sound wave. However the tendency towards nearly synchronous re sponse from a group of fibers is very strong (61) From the third neuron onwards synchronization is less *precise due to variations in* synaptic delay

If the ear is exposed to a steady tone, the discharge frequency of a second-order neuron falls off to fifty percent or even less of the original rate, *within a short time. After* adaptation a steady discharge rate is maintained by most neurons.

From these few features discussed here it is seen that the original frequency is not transmitted along the orderly arranged pathways to the auditory cortex, which also shows regular frequency arrangement, but it is evident that some coding is involved, which has been studied extensively (64–71 et al.)

A further feature which deserves attention is that first-order neurons (34 72–75) and second order neurons (61 76) are frequency *selective At a certain frequency* to which a certain neuron seems to be tuned, less acoustic energy is required to set up impulses. At rather low sound intensities tuning is very sharp. If the intensity is raised the response extends more to the low frequency side (61)

Due to the enormous technical difficulties when trying to single out responses from one of many *thousands of elements crammed into* minute space, and considering superimposed fields an exact answer to the many questions has not been obtained so far Even in the case of the cochlear potential, recording of which is simpler Békésy (77) has cautioned not to interprete findings too literally

The above very brief description gives *only* a rather general idea *of the very involved* mechanism features and problems of neural performance to which those of synaptic mechanisms have to be added. In addition to the references cited above, *standard handbooks* (54 58 59 78–82) may be helpful.

Experimental Procedure

The investigations were carried out on the ear system of the water buffalo (*Anoa bubalis*) as found in Pakistan. The reasons for this selec tion were

(1) The dimensions of the parts to be investigated are so small in ordinary laboratory animals, like white rat, cat, rabbit, and guinea pig, that it seemed desirable to choose the ear system of the biggest animal conveniently available for investigation.

(2) The treatment of the parts to be investigated involves the danger of considerable distortion or even damage to the parts after slaughter of the animal, during fixation and further processing. It was assumed that the bigger and, therefore, more rigid system of the ear of the water buffalo would develop less distortion and retain its normal shape better than the smaller ones.

(3) Large numbers of samples had to be investigated, firstly to develop a suitable technique and secondly to increase the accuracy of the results. Therefore, the availability of specimen in sufficient number had to be assured.

(4) The ear system of water buffalo was available immediately after slaughter of the animal. This was necessary because otherwise post-mortem changes might have taken place distorting the specimen and thus affecting the results of investigations in uncertain manner

(5) It was expected that the dimensions of inner ear of the water buffalo are similar to those of the human ear and, therefore, would permit convenient comparison of data.

To verify the point (5) above, a survey of the outer and of the middle ear system and of the general dimensions of the inner ear of the water buffalo was made before investigating the details of the cochlear partition. This sur vey also permitted, later the assessment of shrinkage of test pieces during processing. Re sults of these measurements are given in Table I. For convenient comparison the dimensions of the human ear have been entered.

Tissue technique

The description hereunder is restricted to few important aspects only

The time between slaughter of the animal and placing of tissue in fixation solution was reduced to about 15 min. A minimum delay is of utmost importance to avoid post-mortem de terioration (83) Before fixation the volume of bone was reduced as much as possible to enhance fixation and decalcification speed.

The fenestra rotunda and the footplate of the stapes were opened under fixation solution *very carefully* avoiding any pressure on the perilymph within the scalae. Then the scalae were flushed repeatedly restricting the column of the flushing solution to 3 to 6 mm.

The fixation solution suggested by Wittmaack (84) was modified to contain double distilled water = 185 ml, $K_2Cr_2O_7$ = 4.25 g, HCHO = 10 ml, CH_3COOH = 5 ml, OsO = 0 7 g. The fixation solution was mixed immediately before use, and fixation was effected in the dark to avoid formation of artificial pigments, and to reduce side effects regarding solubility of precipitated proteins. Fixation time was 48 hours, changing the first solution after 24 hours. The temperature was kept at 25 C.

The test piece was then washed under running water for 24 hours.

Decalcification was effected with 300 ml of 7.5 % HNO_3, the solution was replaced daily by a fresh one, and decalcification lasted 8 days. The tissue was suspended in the upper part of the solution

For exact and convenient embedding of specimen a plane was cut on the bone through the vestibular apparatus and about 5 mm from the stapes.

Before dehydration the specimen was placed in 300 ml of 5 % Na_2SO_4 for 24 hours, and then washed under running water for the same period

Dehydration was started with a 30 % alcohol solution containing 1 % phosphotungstic acid *to forestall later collection of the previously* hydrated fiber-colloids during the concentrated alcohol steps (85) The 30 % and 50 % steps of 6 hours each were followed by 60 70 80 90 and 96 % alcohol water mixtures and two steps of absolute alcohol each step lasting 24 hours. Dehydration was carried out in dark.

The tissue was cleared in two changes of pure 100 % benzene each lasting 24 hours, and this was followed by 48 hours of infiltration *in benzene which was saturated with* paraffin of 58 C melting point. Two changes of molten paraffin (58 C melting point) followed each of 24 hours, and using about 250 ml pure paraffin each time

The test piece was placed on its orientation plane in a cylindrical aluminium container in the last bath, and then the container was placed in cold water To ensure uniform solidification of the paraffin its upper layer was kept molten until the lower part had solidified.

A rotary microtome was employed for sectioning. Because of the distance of pillars and transducers sections were made 10 micron thick. The samples were cut from the apex to the base of the cochlea in this way the delicate structures of the organ of Corti are supported by the basilar membrane Figs. 6–11 show an *increasing compression* of the architectural structure within the organ of Corti from stapes to apex, and which gets less compensated in the same direction by *natural elasticity of the* structures during flattening of paraffin sections during mounting

To be able to produce *the considerable number* of high quality sections required without the lengthy procedure of celloidin embedding, the somewhat complicated cellulose tape method suggested by Palmgren (86) was simplified considerably *(87) Such cellulose tape* sections behave like celloidin sections and are therefore very little compressed by the cutting force of the microtome knife They do, therefore, not show the interesting effect of standard paraffin sections, which was discussed above, but they conceal this property of gradually varying elasticity along the cochlear partition. *However* this change of elasticity of structures is of great interest and will be dealt with in detail in the text For this reason an adequate number of normal paraffin sections was made.

For staining either molybdenum hematoxylin *(83 88) or molybdenum hematoxylin* combined with picro fuchsin was used

Physical measurements

*All parts were measured with an ocular micro*meter employing magnifications of 125 400 and 900 times, according to size of the part to be measured Oil immersion and a suitable illuminator and filter sets to obtain near monochromatic illumination of short wavelength was used for the highest magnification.

To obtain a clear and complete picture of the interaction of the different parts of the system and of their dimensions as a function of the distance of the place of measurement from the stapes, investigations were made at a distance of 10 19 25 30 33 and 36 mm from *the stapes If proper* measurement of length of individual structures seemed to be difficult due to bending of the part to be measured in some test specimen this was overcome by reconstructing the architectural structure in precise drawings with the aid of a to-scale photograph of the section and making of a model of soft copper wire which was subsequently straightened

To compensate for physiological deviations in size of individual ear systems, the values for each ear were tabulated separately and the changes in dimensions along the cochlear partition were ascertained individually for each test piece.

Thirty left ears of water buffaloes of about 6 to 9 years age have been studied. The inclusion of old animals is important because it is believed by some authors (89–92) that the tectorial membrane is only attached to the hairs of the transducers during fetal life

Results of Observations

The results of the measurements of the outer and middle ear system and of the general dimensions of the inner ear are given in Table I The places of measurement are indicated in Fig. 4

As may be seen the main dimensions of the inner ear of *Anoa bubalis* and of man are very similar Some of the dimensions of the outer ear differ These differences suggest an enhanced transmission of lower frequencies by the outer ear of the water buffalo which is of no great importance in connection with the main part of the investigation.

The main part of the investigation, concerning the inner ear has resulted in a clear picture of the interconnection and action of this part of the system

The dimensions of the parts of the cochlear partition are given in Table II In Fig. 5 the places of measurement have been entered, as well as numbers of parts used in the text of Fig. 5 and in later photomicrographs of semi turns of the cochlea

Before discussing dimensional results it seems correct to mention some general observations first.

So far there has been no agreement about any possible interaction between the membrana tectoria and the organ of Corti. Whereas it was generally accepted that the membrana tectoria is attached to the organ of Corti during fetal life (31 41 89-92) the position after birth was not defined

Any detachment of this membrane from the other portion of the cochlear partition must change the physical properties of the inner ear considerably Such change has not been reported in literature. On the contrary it has been established that the animal and human fetus responds to acoustic stimulation in the form of reflexes. Further electric responses can be recorded at fetal inner ears (92) This proves that the inner ear is fully functioning at the time when the tectorial membrane is accepted to be attached.

This investigation shows that the tectorial membrane is a functional part of the entire system of the cochlear partition. Any detachment of this membrane from the organ of Corti is caused by inadequate tissue technique. The solution and method developed in this investigation minimizes this disadvantage and detachment occurs only near to the stapes

This means that the force of contraction due to shrinkage is greater towards the stapes This can be explained by the fact that the number of fibers is greater there and their diameter is greater near to the stapes. Therefore the total cross-section and force of contraction of fibers is increasing towards the stapes.

Due to this variation the stiffness of the membrana tectoria increases towards the stapes This is borne out by experiments in the direction of decreasing stiffness, i e towards the apex, the deformation of the membrana tectoria increases under the sectioning force of the microtome knife

In a detached membrana tectoria the considerable number of fibrils which are oriented in a particular way (cf Fig. 2) would not make much sense It would thus seem rather doubtful what purpose this structure serves, being in the way of hydraulic waves coming from the scala vestibuli through the scala media to the organ of Corti. If the tectorial membrane would not be connected to the organ of Corti it would only consume valuable energy without serving any useful purpose

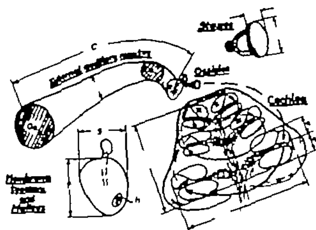

Fig. 4 Schematic drawing of the parts of the outer, middle, and inner ear indicating the parts measured and given in Table I. Also semiturns I–VI are shown, where detailed dimensions of all essential parts of the cochlear partition have been obtained, which are contained in Table II.

Furthermore, the tectorial membrane is formed rather early by the epithelial cells, during the development of the human or animal body. This indicates that it is an essential part.

The orientation of the fibrils in the main body of the tectorial membrane runs obliquely towards the apex of the cochlea, at an angle of about 20°. This construction which has

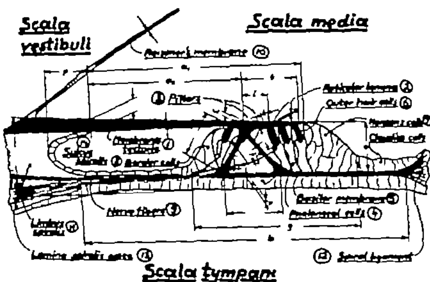

Fig. 5 Schematic section of the organ of Corti indicating places of measurement. This section shows the third semiturn in scale of 200:1. The gap between the membrana tectoria (1) and the reticular lamina (2) is about 1 to 2 micron wide.

(1) Membrana tectoria (2) Reticular lamina
(3) Pillars (4) Phalangeal cells
(5) Basilar membrane (6) Outer hair cells
(7) Hensen cells (8) Border cells
(9) Nerve fibers (10) Reissner' membrane
(11) Limbus spiralis (12) Spiral ligament
(13) Lamina spiralis ossea (14) Sulcus spiralis

From the dimensions of the parts, which have been determined for six places along the cochlear partition, precise reconstruction of the instrument is possible. For dimensions please refer to Table II.

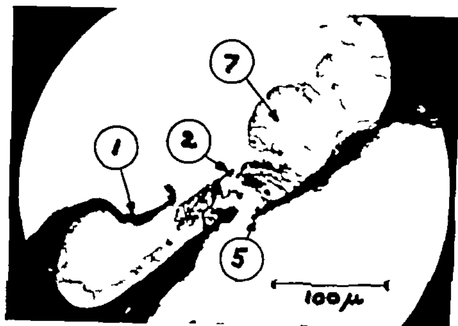

Fig 6 First semiturn of 10-year old buffalo. Magnification ~66 times. Membrana tectoria (1) is torn lose from the organ of Corti. The reticular lamina (2) is also torn. Attention is invited to the cells of Hensen and of Claudius (7), which are far more bulky than the organ of Corti. The thickness of the basilar membrane (5) is not uniform.

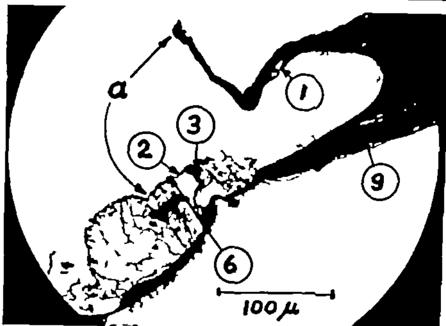

Fig 7 Second semiturn of same test piece. The reinforcing fibers within the tectorial membrane are clearly seen (1). Similarly these fibers are to be seen in the reticular lamina (2) and in the head of the pillars (3). Also hairs of outer transducer rows (6) are visible, as well as nerve fibers (9). It is very interesting to note how nicely the end of the tectoria (1) (upper arrow of (a)) fits into the corresponding recess at the outer end of the reticular lamina (lower arrow of (a)). This leaves no doubt about the attachment of the tectorial membrane to the organ of Corti along its entire length.

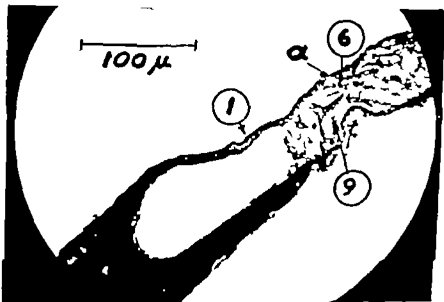

Fig 8 Third semiturn of same specimen. The gap below the tectorial membrane is very well seen at arrow (a). This gap is bridged by the hairs at the upper end of the transducers (6). A nerve fiber with cell body (9) can be seen crossing the tunnel

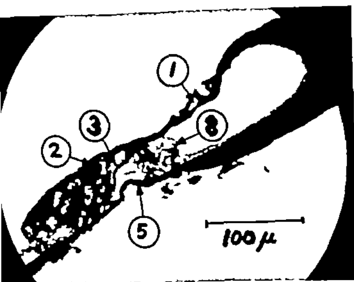

Fig 9 Fourth semiturn. Attention is drawn to the thin reinforcing fibers in the tectoria (1), to the gap bove the reticular lamina (2), the decreased thickness of the basilar membrane (5), and to the bulge at (8). The reason for the bulge is compression during processing of the specimen.

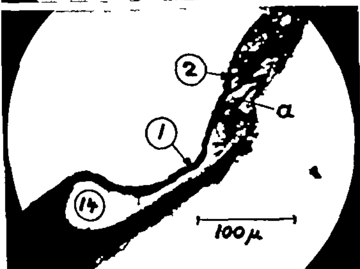

Fig 10 Fifth semiturn. The increase in length f the membrana tectoria (1) compared to Fig. 6 is striking. The membrana reticularis is to be seen at (2), and very clearly the gap between it and the tectoria where the reticularis has bulged inwards (*a*). The length of the sulcus spiralis should be compared with Fig. 6.

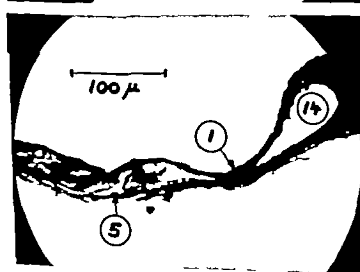

Fig. 11 Sixth semiturn. Here the membrana tectoria (1), as well as the basilar membrane (5) have become rather thin, as compared to the first semiturn. The sulcus spiralis should be noted, it indicates the span of the tectoria.

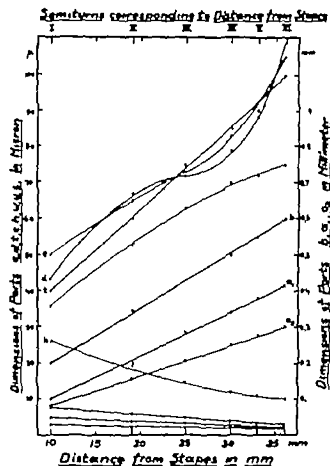

Fig 12 Dimensional changes of the most important parts of the architectural structures of the cochlear partition as a function of the distance of the place of measurement from the stapes.

Roman numerals on the abscissa indicate the distance of the semiturn from the stapes. On the ordinate dimensions are shown in millimeter or in micron according to the size of the part and in accordance with *Table II*

The continuous curves demonstrate the gradual change of dimensions between the stapes and the apex of the cochlea

been noticed by several workers (e g. 37 38 40) but which *has not* been incorporated in theories of hearing has to be considered because it results in anisotropic mechanical properties of the membrane. Such directional elasticity has been observed by Békésy (96) in 1947 but it has not been incorporated in any of the current theories of hearing.

Further experiments show that the dimensions of the membrana tectoria change gradually as a function of the distance of the place of measurement from the stapes The thickness of this membrane decreases from the stapes to the apex, and at the same time the width of the membrane increases in the same direction This can very well be seen in Table II and in Figs 6 to 11 and attention is also invited to Fig. 12 which gives the dimensional changes of the most important parts in graphs.

Due to a rather limited amount of non-orientated (interlacing) fibers (37 38 40) the membrana tectoria possesses considerable anisotropic elasticity as already observed by Békésy (loc cit.) and therefore, can be said to possess the property of an oscillator It can thus be concluded that due to small coupling to adjacent segments *sharp tuning will result.* This means that the natural frequency of the membrana tectoria *will change gradually from* a high value near the stapes to a low one at the apex (helicotrema) and that only a narrow segment will oscillate in resonance with the *frequency of the force* and also at the places of the membrana tectoria corresponding to *higher harmonics* if the sound intensity is of adequate level A detailed discussion will follow later

The length of the pillars (rods of Corti) and *at the same time their angle of inclination* increases progressively from the stapes towards the *helicotrema As their diameter remains* practically constant this features will lower the *natural frequency of the system* towards the apex

The *plate* (reticular lamina) attached to the upper side of the pillars is thicker near the stapes, at the place of reception of the high frequencies, than at the helicotrema. As the *natural frequency* of a plate goes up if its thickness is increased this increase of thickness of the reticular lamina will also raise the natural frequency of the system towards the stapes.

The span of the reticular lamina (cf *l* in Fig. 5 and in Table II) from the point where the pillars meet, outwards, increases as one moves towards the apex If the span of an oscillating plate is raised this will reduce the natural frequency and in the same manner the natural frequency of the system will be lowered towards the apex.

It has been known for at least one and a half century that the span of the basilar membrane increases considerably from the stapes towards the helicotrema. However data for variation of width do not show good agreement and vary from about 1 in 6.26 (97) to about 1 in 12.5 (25). The variation for the water buffalo is about 1 in 12 (Table I) which is in good agreement with most findings concerning the human ear.

The experiments show in addition, that not only the width increases from stapes to apex, but that at the same time the thickness of the basilar membrane decreases. This is a strong argument against any theory which considers the basilar membrane as resonator, as the mass per unit length decreases.

Further the reinforcing influence of the structures of the organ of Corti on the basilar membrane diminishes as one proceeds towards the apex. This is not only confirmed by the dimensions obtained during this investigation (Table II) but by the behaviour of standard paraffin sections, which confirms this physical property. As mentioned earlier the cutting pressure of the microtome knife was directed towards the base of the inner ear. This produced an increasing compression of the architectural structure towards the apex and which was in the same direction less and less compensated by the natural elasticity of the structure. An accidental behaviour during experiments regarding this property has to be ruled out, as each one of the very many experiments produced identical results.

The decrease in stiffness discussed above is also briefly mentioned by Hawkins (38) however there is no general increase in mass from base to apex, as he believes. As uniform density of corresponding parts along the membrane may be taken for granted, it can be derived from the values shown in Table II that the mass of the organ of Corti remains practically constant along the cochlear partition.

As observed by Hawkins (loc. cit.) the length of the transducers increases from the stapes towards the apex.

Studying now Fig. 12 and starting the discussion with the lowest curve for the thickness of the reticular lamina (s) at the first outer row of transducers, it is seen that the reticular lamina is thicker towards the stapes. From Table II one obtains that the increase in thickness from 36 mm from the stapes to 10 mm from the stapes amounts to about 60%.

The thickness of the basilar membrane (u) increases uniformly from 2 micron at semiturn VI to 4.9 micron at semiturn I, i.e. nearly two and a half times.

The curves for (w) and (h) may be considered together both give the thickness of the membrana tectoria. Curve (w) shows the value above the joining place of the pillars, and (h) is the thickness at the important place where this membrane leaves the limbus spiralis, i.e. from where its free span measures. It is seen that the thickness increases continuously from the apex to the stapes. The increase for (h) from semiturn VI to I is 260%. This increase is not quite linear along the cochlear partition, as the curves show. The curve for (h) is very important in connection with determining the natural frequency of the tectorial membrane.

The graph for (a_2) illustrates the increasing span of the membrana tectoria from the place where it leaves the limbus spiralis to the place above the junction of the pillars. The increase is practically linear. The span is nearly 3.5 times greater at the sixth semiturn compared to the value at semiturn I.

The full free span of the membrana tectoria is designated with (a_1). It is seen that the increase is nearly linear and that the span at semiturn VI is 4.. times greater than at semiturn I. The free span is of utmost importance in connection with the natural frequency of this membrane. Details in this connection will be discussed in the next chapter.

The width of the basilar membrane progresses practically linearly from semiturn I to semiturn VI, as may be seen by inspecting the graph for (b). The value of 0.6 mm at semiturn VI is in agreement with the measurements of the main dimensions of the inner ear shown

in Table I If the curve for *(b)* is extrapolated to the left, good agreement for the width of the basilar membrane is obtained at the stapes with the value shown in Table I (0 05 mm)

The length of the inner pillar has been de signated as *(c)* that of the outer one as *(d)* and the distance between the feet of the pillars as *(e)* Also these dimensions change progres sively These dimensions are interesting in as much as they permit a study of the compression of the structures of the organ of Corti under the cutting force of the microtome knife, as mentioned earlier

Finally the span of the tectorial membrane from the junction of the pillars to the outer edge of the third row of transducers is shown as *(t)* Again a linear change is observed.

It is fascinating to note the very precise construction of all these parts of the inner ear This would never be so if no specific purpose would exist for this exact design of each part.

In spite of physiological deviations between individual ears, practically identical physical characteristics have been observed in the 30 test pieces investigated The lesser thickness of the tectorial membrane of some test pieces was accompanied by smaller spans, resulting in similar functions of the natural frequency along the cochlear partition

Discussion and Comparison of a New Approach to Theory of Hearing with Observations and with Older Theories

The results of the experiments lead to a new approach to theory of hearing and a new interpretation of the functioning of the ear can be put forward in the form of the following cybernetic model.

The oscillations of the perilymph in the scala vestibuli (cf. Fig. 5) are imparted through the membrane of Reissner to the endolymph in the scala media. Those parts of the membrana tectoria, the natural frequency of which corresponds to the frequency of the force, pick up the vibrations, and due to a certain amount of damping and coupling, neighbouring areas will also vibrate. Assuming a pure tone, only a rather narrow segment of this membrane will respond due to its anisotropic mechanical properties, and rather sharp tuning will result.

The oscillations of the membrana tectoria are imparted to the hairs (stereocilia) of the transducers (hair cells) which are connected with it, and these stiff transmitter pins (38) act on a diaphragm (cuticular plate). This closes the upper side of the transducers. For a mechanical interpretation, the transducers may be regarded as a tube which is filled with cytoplasm and closed at the upper end by a diaphragm acting like a piston on the contents of the tube.

The upper rim of each tube (transducer) is firmly mounted to a supporting frame-plate (reticular lamina) and which rests on the pillars and, to a certain extent on the border cells, and cells of Hensen which are connected to the inner and outer edge of the plate, and on the extensions of the phalangeal cells. The pillars are in turn supported on their lower side by the basilar membrane and the cell layer covering it (connective tissue) This membrane also lends support to the outer and inner cells mentioned above.

The lower part of each transducer is supported by a reinforced structure (phalangeal cell) and this rests on the basilar membrane.

This design corresponds to the most efficient possible use of the transducers, as strain built up within them is not impeded by other cells and they are freely accessible to the electrolyte at their circumference.

The direction of the fibrils which reinforce the tectorial membrane (cf. Fig. 2) corresponds to the oblique arrangement of the transducers. Therefore, each narrow segment of the tectorial membrane acts on a corresponding segment of the transducer rows below For a mechanical model the tectorial membrane may be considered as a long row of oscillating reeds, of progressively changing thickness and span, *built like a reed-type frequency meter however in a more involved way*

The gap between the tectorial membrane and the membrana reticularis and the diaphragm closing the upper side of the transducers (*cuticular plate*) is bridged by transmitter pins (hairs of hair-cells) This gap ensures that the tectorial membrane may oscillate undisturbed at low or medium sound intensities. At high sound intensities, which cause amplitudes approaching the order of the gap's size, the design protects the delicate transducers, because then the gap commences to act like a hydraulic shock absorber

Studying the design of energy transmission

in Table I If the curve for *(b)* is extrapolated to the left, good agreement for the width of the basilar membrane is obtained at the stapes, with the value shown in Table I (0 05 mm)

The length of the inner pillar has been designated as *(c)* that of the outer one as *(d)* and the distance between the feet of the pillars as *(e)* Also these dimensions change progressively These dimensions are interesting in as much as they permit a study of the compression of the structures of the organ of Corti under the cutting force of the microtome knife as mentioned earlier

Finally the span of the tectorial membrane from the junction of the pillars to the outer edge of the third row of transducers is shown as *(f)* Again a linear change is observed.

It is fascinating to note the very precise construction of all these parts of the inner ear This would never be so if no specific purpose would exist for this exact design of each part.

In spite of physiological deviations between individual ears, practically identical physical characteristics have been observed in the 30 test pieces investigated. The lesser thickness of the tectorial membrane of some test pieces was accompanied by smaller spans, resulting in similar functions of the natural frequency along the cochlear partition.

Discussion and Comparison of a New Approach to Theory of Hearing with Observations and with Older Theories

The results of the experiments lead to a new approach to theory of hearing and a new interpretation of the functioning of the ear can be put forward in the form of the following cybernetic model.

The oscillations of the perilymph in the scala vestibuli (cf. Fig. 5) are imparted through the membrane of Reissner to the endolymph in the scala media. Those parts of the membrana tectoria, the natural frequency of which corresponds to the frequency of the force pick up the vibrations, and due to a certain amount of damping and coupling, neighbouring areas will also vibrate. Assuming a pure tone, only a rather narrow segment of this membrane will respond due to its anisotropic mechanical properties, and rather sharp tuning will result.

The oscillations of the membrana tectoria are imparted to the hairs (stereocilia) of the transducers (hair cells) which are connected with it, and these stiff transmitter pins (38) act on a diaphragm (cuticular plate) This closes the upper side of the transducers. For a mechanical interpretation, the transducers may be regarded as a tube which is filled with cytoplasm and closed at the upper end by a diaphragm acting like a piston on the contents of the tube.

The upper rim of each tube (transducer) is firmly mounted to a supporting frame-plate (reticular lamina), and which rests on the pillars and, to a certain extent on the border cells, and cells of Hensen which are connected to the inner and outer edge of the plate, and on the extensions of the phalangeal cells. The pillars are in turn supported on their lower side by the basilar membrane and the cell layer covering it (connective tissue) This membrane also lends support to the outer and inner cells mentioned above

The lower part of each transducer is supported by a reinforced structure (phalangeal cell) and this rests on the basilar membrane

This design corresponds to the most efficient possible use of the transducers as strain built up within them is not impeded by other cells and they are freely accessible to the electrolyte at their circumference.

The direction of the fibrils which reinforce the tectorial membrane (cf Fig. 2) corresponds to the oblique arrangement of the transducers. Therefore each narrow segment of the tectorial membrane acts on a corresponding segment of the transducer rows below For a mechanical model the tectorial membrane may be considered as a long row of oscillating reeds, of progressively changing thickness and span, built like a reed-type frequency meter however in a more involved way

The gap between the tectorial membrane and the membrana reticularis and the diaphragm closing the upper side of the transducers (cuticular plate) is bridged by transmitter pins (hairs of hair-cells) This gap ensures that the tectorial membrane may oscillate undisturbed at low or medium sound intensities. At high sound intensities, which cause amplitudes approaching the order of the gap's size, the design protects the delicate transducers, because then the gap commences to act like a hydraulic shock absorber

Studying the design of energy transmission

from the tectorial membrane to the cuticular plate through the transmitter pins, it is seen that this design increases the efficiency of the system, as the corresponding area of a segment of the membrana tectoria is about twice as big as the area of the cuticular plates, as may be seen from surface preparations of the organ of Corti (41 42 cf Fig 2) The effect is, therefore, comparable to the one produced by the difference in area between drum and the footplate of stapes

The displacements of the diaphragm closing the top of the transducers, act on the practically incompressible cytoplasm which in turn transmits the pressure changes to the walls of the transducers and to the fine nerve endings there

Stretching of highly polymerized chain compounds, changes their chemical properties (98) and may well induce electrochemical processes besides affecting the inter-molecular fields of forces. Stretching of a muscle causes a signal in the nerve endings in it (e g. patellar reflex) The strain in transducer wall and nerve sections attached to it, which is caused by the displacement of the contents of the transducer causes an electrical phenomenon which leads to a transmission of a signal to the auditory areas of the brain.

Some theories, like the Helmholtz theory of hearing, stipulate membranes under tension During the investigations discussed here no tensions could be found to exist on the contrary there seems to exist some loose play in the basilar membrane towards the apex It is apparent that no parts under continuous internal stress are required to explain this theory of hearing. On the other hand, the vibrating system is immersed in a liquid the relative density (31 32) of which is nearly identical to that of the other parts of the system with the result that buoyancy counteracts gravity This is an important fact in view of the extremely delicate design of the system and this does not only eliminate continuous stress but also insures identical behaviour of the system irrespective of the position of the head

As the parts of the inner ear system are not exposed to loads when at rest the many reinforcements within the various parts may be taken to indicate that they are designed to operate under dynamic forces, which interpretation sounds reasonable if one considers that the inner ear has to process hydraulic oscillations, i.e dynamic events.

Thus, when interpreting the physical behaviour of the system as described above, the intricate design of each single part and the interconnection of all parts become obvious. The objection raised against most of the theories of hearing proposed until now is that they do not consider the complicated design of the cochlear partition, which is now utilized to explain the function of the ear in a better way and seems to be confirmed by the results of this investigation. Each part of the system is required to fulfil a specific purpose and action, it is not anymore necessary to stipulate undefined analysing mechanisms as sometimes resorted to until now (99–103) and that the performance of the hearing instrument can now be well understood. (A detailed discussion of theories of hearing and of problems arising out of them will be published in a separate paper) Therefore this cybernetic model, so-called because the hearing instrument is employed to analyse and to transmit information (104–108) in which the anisotropic tectorial membrane represents a series of tuned reeds acting on segmented rows of transducers, including their suspension and all other parts, is so excellently designed by nature that it seems very difficult to suggest any improvement of the instrument

From the experimental data given in Table II the natural frequency of the tectorial membrane was calculated as a function of the distance from the stapes. For this purpose the tectorial membrane was considered like a series of bars. This approach was adopted because of the anisotropical properties observed by Békésy (96) which show a rather narrow segment of depression even under excessive load and because this property is fully confirmed by the

arrangement of the reinforcements in the membrane (loc. cit.) Under normal sound intensities a very much narrower segment will be affected than by the heavy load applied by Békésy and which permits treatment of individual sections like bars, at least to a first approximation.

The physical properties of the parts described above indicate that attention has to be focused on the membrana tectoria, although one will have to consider a number of contributing factors which will influence the natural frequencies of the structure along the cochlear partition. Such factors are the progressively decreasing moment of inertia of the membrana reticularis towards the apex, the similarly decreasing restoring force exercised by the pillars, and the cross section of the fibers reinforcing the membrana tectoria which decreases progressively towards the apex.

Whereas the first factors do not appear to change the characteristics of the oscillating system very much, the last one will have to be considered.

In view of the oblique arrangement of the reinforcing fibers within the tectoria (cf. Fig.) the measured values of the oscillating span of this membrane (a) as shown in Table II have been divided by cos 20 = 0.94

For the evaluation of the natural frequency of the tectorial membrane at each place of measurement, the following general formula has been used.

$$n_e \sim c(1\ f) \qquad (1)$$

where n_e is the natural frequency, c is a constant, and f is the deflection of the bar under load. For a rectangular bar clamped at one side the deflection is:

$$f \sim P\ P\ \alpha\ E\ I \qquad (2)$$

Where P is the load, l is the length of the bar, α is a constant, E is Young's modulus, and I is the moment of inertia given by the relation:

$$I = b\ h^3\ 12 \qquad (3)$$

where b is the width of the bar, h is the height.

Inserting equation (3) in equation (2) and then in equation (1) the natural frequency for a square bar ($b = h$) is:

$$n_e \sim C_I\ h^2/l^3 \qquad (4)$$

where C_I is a constant, h is the height of the oscillating bar and l is its length.

A somewhat different formula is used for calculating the natural frequency of tuning forks (109):

$$n_e \sim C_{II}\ h/l^2 \qquad (5),$$

where C is a constant, which is similar to formulas for round bars used in engineering handbooks (110)

The subsequent calculations are based on above formulas (4), and (5) and the results are shown in Table III and in Fig. 13 where also the values observed for the human ear have been entered to permit comparison. A discussion of the curves will follow later after discussion of the correction factor needed to allow for the change in reinforcements within the tectorial membrane.

The dimensions used in the calculations are as follows (cf. Table II) according to the distance of the place of measurement from the stapes (values are stated in micron):

Semiturn	I	II	III	IV	V	VI
h (μ)	26	20	15	12	11	10
a_1 (μ)	100	200	290	340	380	420
l (μ)	106	212	308	362	404	447

The thickness is h and a the free span of the membrana tectoria vertical to the direction from stapes to apex, and $l = a_1/\cos 20$ as mentioned earlier.

The constants have been chosen in such a way as to produce a natural frequency of 40 cps for semiturn VI, i.e. about 36 mm from the stapes.

The following Table III shows the natural frequency of the tectorial membrane along the cochlear partition as calculated by formulas (4) and (5)

from the tectorial membrane to the cuticular plate through the transmitter pins, it is seen that this design increases the efficiency of the system as the corresponding area of a segment of the membrana tectoria is about twice as big as the area of the cuticular plates, as may be seen from surface preparations of the organ of Corti (41 42 cf Fig 2) The effect is, therefore comparable to the one produced by the difference in area between drum and the footplate of stapes

The displacements of the diaphragm closing the top of the transducers, act on the practically incompressible cytoplasm which in turn transmits the pressure changes to the walls of the transducers and to the fine nerve endings there

Stretching of highly polymerized chain compounds, changes their chemical properties (98) and may well induce electrochemical processes, besides affecting the inter molecular fields of forces Stretching of a muscle causes a signal in the nerve endings in it (e.g. patellar reflex) *The strain in transducer wall and nerve sections attached to it, which is caused by the displacement of the contents of the transducer causes an electrical phenomenon which leads to a transmission of a signal to the auditory areas of the brain.*

Some theories, like the Helmholtz theory of hearing, stipulate membranes under tension. During the investigations discussed here no tensions could be found to exist, on the contrary there seems to exist some loose play in the basilar membrane towards the apex It is apparent that no parts under continuous internal stress are required to explain this theory of hearing. On the other hand the vibrating system is immersed *in a liquid the* relative density (31 32) of which is nearly identical to that of the other parts of the system, with the result that buoyancy counteracts gravity This is an important fact in view of the extremely delicate design of the system *and this does not* only eliminate continuous stress but also insures identical behaviour of the system irrespective of the position of the head.

As the parts of the inner ear system are not exposed to loads when at rest the many reinforcements within the various parts may be taken to indicate that they are designed to operate under dynamic forces, which interpretation sounds reasonable if one considers that the inner ear has to process hydraulic oscillations, i e dynamic events

Thus, when interpreting the physical behaviour of the system as described above the intricate design of each single part and the interconnection of all parts become obvious. The objection raised against most of the theories of hearing proposed until now is that they do not consider the complicated design of the cochlear partition, which is now utilized to explain the function of the ear in a better way and seems to be confirmed by the results of *this investigation* Each *part* of the system is required to fulfil a specific purpose and action it is not anymore necessary to stipulate undefined analysing mechanisms as sometimes resorted to until now (99–103) and that the *performance of the hearing instrument* can now be well understood (A detailed discussion of theories of hearing and of problems arising out of them will be published in a separate paper) Therefore, this cybernetic model, so-*called because the hearing instrument* is em-*ployed to analyse and to transmit information* (104–108) in which the anisotropic tectorial membrane represents a series of tuned reeds acting on segmented rows of transducers, in-*cluding their suspension and* all other parts, is so excellently designed by nature that it seems very difficult to suggest any improvement of the instrument.

From the experimental data given in Table *II the natural frequency of the* tectorial membrane was calculated as a function of the distance from the stapes. For this purpose the tectorial membrane was considered like a series of bars. This approach was adopted because *of the anisotropical properties* observed by Békésy (96), which show a rather narrow segment of depression even under excessive *load* and because this property is fully confirmed by the

stapes. It is seen that the values agree very well with the observations on the human ear. This was to be expected from the similarity obtained from the first part of the investigation, and shown in Table I. It is seen that not only the design of the outer ear of *Anoa bubalis* favours selection of lower frequencies, due to the length of the outer acoustic meatus, but that also the design of the membrana tectoria supports discrimination of lower frequencies.

The interlinkage of the parts of the architectural structures of the cochlear partition as well as their physical properties does not only permit a reasonable explanation of the mode of functioning of the system but also the values calculated from dimensions obtained from the experiments are in agreement with observations.

The result of the calculation is of great interest in connection with an observation of Békésy (111). When studying the shift of the maximum of the envelope of the displacement of the cochlear partition according to a given ratio of frequency change, Békésy has observed that the mechanical resolving power of the cochlea of the cow favours the lower frequencies.

Different theories of hearing available so far are to a considerable extent *ad hoc* relative to few phenomena only. Therefore, it will be interesting to see that this theory of hearing does not have this disadvantage, and is able to explain most of the essential observations about the behaviour of the ear. In the subsequent pages these physical problems will be discussed in the light of this theory.

A. Shape of resonance curves observed by Békésy

Békésy (111) determined the locus of maximum displacement of the cochlear partition as a function of the frequency for various animals and found curves which were similar. However, he observed that the curves for the elephant are more pointed, a phenomenon which was not investigated further.

As the intensities of tones, which are required for making direct observations are very high and mostly above the threshold of feeling, pronounced harmonics will appear which disturb the simple resonance curve. This is quite obvious as the amplitude of the basilar membrane at sound pressure of 10^3 dyne/cm² which is about the upper limit the ear can tolerate, is about 10^{-4} cm (112). The absolute threshold of hearing has been found to cause an amplitude of about 10^{-11} cm (25). In view of the experimental difficulties the accuracy of observation will improve with the size of the investigated object and it is safe to assume that the pointed curve observed by Békésy in the inner ear of the elephant represents the true performance of the cochlear partition to a greater extent than what one would believe to observe in the smaller specimens.

The pointed peak of resonance observed by Békésy in the biggest specimen supports the view deduced from this investigation, that most of the frequency analysis takes place in the inner ear, and that coupling to adjacent segments of the tectoria is small.

B. Difference in relative elasticity of the parts of the cochlear partition

Békésy did not incorporate the difference in relative elasticity observed by him (96) into a physical interpretation of the performance of the individual parts of the system but considered the cochlear partition as one part.

Békésy's observations are confirmed qualitatively and quantitatively by the observations and theory discussed here. Comparing the pronounced elasticity of the tectorial membrane with the rigid girder-like partition, it is evident that static as well as oscillatory deflections of the tectorial membrane must be very much bigger than those of the basilar membrane reinforced by the architectural structure erected on the top of it. This is shown by the following calculation for the third semiturn, where dimensions have been shown in Fig. 14.

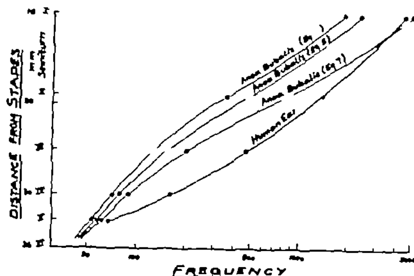

Fig 13 Diagram of natural frequencies of the tec torial membrane of water buffalo which have been calculated on the basis of data obtained during this investigation, and applying three alternative formulas.

For comparison the frequency curve for the human ear has been shown.

It is seen that the frequency curves of the buffalo agree well with the one of the human ear It is noted that the ear of water buffalo favours frequency selectivity in the lower frequency range. This property of the inner ear of the water buffalo agrees with findings during this investigation regarding the outer ear (Table I). This indicates that both sections are designed according to an identical teleological aim.

Table III
Values in cps

Semiturn	I	II	III	IV	V	VI
Formula (4)	2 330	448	157	79	57	40
Formula (5)	1 860	356	1 7	74	54	40

Reverting to formulas (1) and (2) it is seen that

$$n \approx c(a\ E\ I/P\ l^4)^{\frac{1}{2}} \qquad (6)$$

The letters used in the above equation correspond to those of formulas (1) and (2)

This equation shows that the natural frequency of an oscillating structure depends on its moment of inertia. As the cross section of the reinforcing fibers in the membrana tectoria changes with the distance from the stapes, formula (4) will have to be amended in such a way as to permit a correction of the frequencies shown in Table III when considering this factor

The axial moment of inertia depends on the mass of the homogenous body times the square of its distance from the axis, or translated to our case dealing with the cross sections of the fibers, the axial moment of inertia depends on the cross section areas multiplied by the square of their distance Here only the latter has to be considered, and the formula corrected to include this influence will be·

$$n_e \approx C_I\ h^2\ F^{\frac{1}{2}}/l^2 \qquad (7)$$

where F is the area of the reinforcing fibers. The other symbols correspond to those used in the preceding formulas. Table IV shows the natural frequencies of the tectorial membrane from semiturn I to VI as calculated and corrected for the increasing area (F) of the reinforcing fibers within this membrane as obtained from measurements.

Table IV

Semiturn	I	II	III	IV	V	VI
F (units)	4 45	3 13	1 65	1.25	1 13	1
$F^{\frac{1}{2}}$ (units)	2.10	1 77	1.28	1 12	1 06	1
n (cps)	4 890	865	201	88	60	40

The values of the natural frequencies of the tectorial membrane of the water buffalo derived from formulas (4) (5) and (7) are shown in Fig 13 according to the distance from the

stapes. It is seen that the values agree very well with the observations on the human ear. This was to be expected from the similarity obtained from the first part of the investigation, and shown in Table I. It is seen that not only the design of the outer ear of *Anoa bubalis* favours selection of lower frequencies, due to the length of the outer acoustic meatus, but that also the design of the membrana tectoria supports discrimination of lower frequencies.

The interlinkage of the parts of the architectural structures of the cochlear partition as well as their physical properties does not only permit a reasonable explanation of the mode of functioning of the system, but also the values calculated from dimensions obtained from the experiments are in agreement with observation.

The result of the calculation is of great interest in connection with an observation of Békésy (111). When studying the shift of the maximum of the envelope of the displacement of the cochlear partition according to a given ratio of frequency change, Békésy has observed that the mechanical resolving power of the cochlea of the cow favours the lower frequencies.

Different theories of hearing available so far are to a considerable extent *ad hoc* relative to few phenomena only. Therefore, it will be interesting to see that this theory of hearing does not have this disadvantage, and is able to explain most of the essential observations about the behaviour of the ear. In the subsequent pages these physical problems will be discussed in the light of this theory.

A. Shape of resonance curves observed by Békésy

Békésy (111) determined the locus of maximum displacement of the cochlear partition as a function of the frequency for various animals and found curves which were similar. However, he observed that the curves for the elephant are more pointed, a phenomenon which was not investigated further.

As the intensities of tones, which are required for making direct observations are very high and mostly above the threshold of feeling, pronounced harmonics will appear which disturb the simple resonance curve. This is quite obvious as the amplitude of the basilar membrane at sound pressure of 10^3 dyne/cm^2 which is about the upper limit the ear can tolerate is about 10^{-4} cm (112). The absolute threshold of hearing has been found to cause an amplitude of about 10   cm (25). In view of the experimental difficulties the accuracy of observation will improve with the size of the investigated object and it is safe to assume that the pointed curve observed by Békésy in the inner ear of the elephant represents the true performance of the cochlear partition to a greater extent than what one would believe to observe in the smaller specimens.

The pointed peak of resonance observed by Békésy in the biggest specimen supports the view deduced from this investigation, that most of the frequency analysis takes place in the inner ear and that coupling to adjacent segments of the tectoria is small.

B. Difference in relative elasticity of the parts of the cochlear partition

Békésy did not incorporate the difference in relative elasticity observed by him (96) into a physical interpretation of the performance of the individual parts of the system but considered the cochlear partition as one part.

Békésy's observations are confirmed qualitatively and quantitatively by the observations and theory discussed here. Comparing the pronounced elasticity of the tectorial membrane with the rigid girder-like partition, it is evident that static as well as oscillatory deflections of the *tectorial* membrane must be very much bigger than those of the basilar membrane reinforced by the architectural structure erected on the top of it. This is shown by the following calculation for the third semiturn, where dimensions have been shown in Fig. 14.

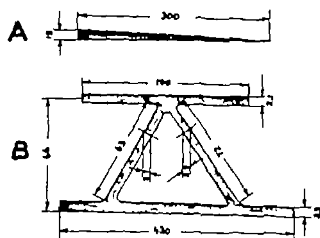

Fig 14 Schematic diagram showing the main architectural parts of the cochlear partition, with dimensions in micron for the third semiturn of the water buffalo

(A) shows the membrana tectoria s cross section, and (B) the lattice girder the base of which is the basilar membrane. On this base two rows of pillars stand which carry the membrana reticularis. The moment of inertia of the lattice girder only is nearly fifty times greater than that of the membrana tectoria It is obvious that under a static as well as under a dynamic force the deflection of the lattice girder will be much smaller than that of the tectorial membrane.

(1) Moment of Inertia of the Membrana Tectoria

$I_t = a_1 \; h^3/36 = 300 \times 15^3/36 = 28\,000$ units

(2) Moment of Inertia of the Lattice Girder

$I_{lg} = \sum I + f \; r^2$

i e the moment of inertia of the lattice girder is equivalent to the sum of the moment of inertia of the individual parts and of the area of the individual parts times the square of their distance to the axis

If the axis is taken parallel to the basilar membrane and through the center of gravity of the lattice girder a moment of inertia of about 1 000 000 units results which is about 35 times more than the moment of inertia of the tectorial membrane Actually the difference is more pronounced because the connective tissue on the lower side of the basilar membrane and other cells on top of the basilar membrane will increase the moment of inertia of the architectural structure

Considering these additional parts the difference in moment of inertia is of the same order as the difference in deflections observed by Békésy under static load (cf formula (2) regarding dependence of deflection on moment of inertia)

C. Frequency selectivity of the ear

The envelope of deflections of the basilar membrane (113 114) on which many present theories of hearing are based shows an extremely flat peak. At a sound intensity of 134 db the ratio of the height of the peak exceeding 50% of the amplitude to the length of this bulge is about 1 in 6 000! This makes it impossible to ascribe the rather delicate tuning of the ear to this envelope The peak of the basilar membrane exceeding 50% of the relative amplitude covers some octaves. This feature is one of the strongest arguments against place theories of hearing in their present form It may be suggested here that the damping of the basilar membrane is also too big to permit delicate tuning of the instrument, because one has to consider the many attached elements (cf Fig. 5) which possess internal friction.

The natural frequency of a resonating membrane is affected by its mass. However it is seen when studying cross sections of the cochlear partition that masses (cells of Claudius, cells of Hensen, border cells, connective tissue) are arranged on the basilar membrane in an irregular manner along its length. This is not compatible with the observed delicate tuning of the ear Wien (115 116) has objected to the Helmholtz theory of hearing on similar theoretical reasons stating that the damping coefficient of the basilar membrane as demanded by Helmholtz s theory is not compatible with the observed response of the ear after a tone is switched off Therefore the basilar membrane has to be ruled out as a suitable resonator performing the observed frequency analysis.

The resonance peak of the tectorial membrane is however much narrower and its

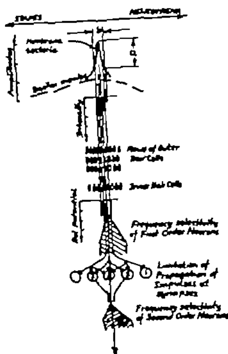

Fig 15 Schematic illustration of frequency limitation of transmitted band. Only the range b will send signals, where the amplitudes are above the minimum required. For sake of clarity phase shift between oscillations of tectoria and reticularis is not shown. The reticular lamina will only be involved at elevated frequencies. The band of signals generated will be narrowed-in at first and at second order neurons and at synaptic connections. The figures in the circles illustrate the number of stimuli arriving at the respective connection.

damping is less pronounced because there are no additional elements arranged on it, like those found on the basilar membrane. Contrary to the basilar membrane its design is very precise, showing very gradual variation of dimensions, as discussed earlier and of masses, with no irregularities or factors exercising an adverse influence. Therefore this theory does not attract the criticism raised by Wien (loc. cit.) against Helmholtz's theory of hearing.

It seems, therefore, possible to suggest an overall frequency analysing mechanism as shown in Fig. 15 Only that sector of the cochlear partition will transmit a signal where the relative displacement, combined with the generation and transmission efficiency of members involved, is above the minimum required. First as well as second order neurons have been found to be frequency selective (34 61 72–76), therefore, the transmitted signal band will be narrowed in. In addition to this a limitation of signal-band propagation will take place at synaptic connections (61–63) as the further transmission of the signal depends on the strength and on the number of signals arriving at synaptic connections.

D Area of maximum stimulus

According to this theory the area of maximum electrical activity (117) corresponds to the resonance peak of the envelope of deflections of the tectoria, which is in accordance with observations. This is not so in other theories where eddies (118–124) are assumed to be responsible for the auditory sensation, as they would appear on the apical side of the deflection.

The width of the area of maximum electrical activity corresponds to the resonance peak of the tectorial membrane, but not to the flat envelope of the amplitudes of the basilar membrane.

E. Sensitivity to frequency shift

The ear is sensitive to a frequency change of about 3 cps (125) This corresponds to a longitudinal shift along the cochlear partition of about $1.3 \times 10^{-}$ cm, as may be established from observations (117 124 126–130) on which the curve for the human ear in Fig. 13 is based. The envelope of the displacement of the basilar membrane is not in a position to explain this phenomenon, because the amount of shift is only about one five hundredth of the length of the extremely flat peak of the deflection exceeding 50% of the relative maximum amplitude. Furthermore, this shift in the longitudinal direction, which is detected by the ear is only about one-sixth of the height of the lattice girder (cf. section B). The observed frequency-shift sensitivity of the hearing instru-

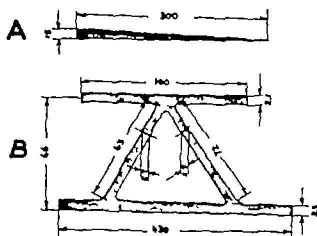

Fig 14 Schematic diagram showing the main architectural parts of the cochlear partition, with dimensions in micron for the third semiturn of the water buffalo

(A) shows the membrana tectoria s cross section, and (B) the lattice girder the base of which is the basilar membrane. On this base two rows of pillars stand which carry the membrana reticularis. The moment of inertia of the lattice girder only is nearly fifty times greater than that of the membrana tectoria It is obvious that under a static as well as under a dynamic force the deflection of the lattice girder will be much smaller than that of the tectorial membrane.

(1) Moment of Inertia of the Membrana Tectoria.

$I_t = a_1 \; h^3/36 = 300 \times 15^3/36 = 28\,000$ units

(2) Moment of Inertia of the Lattice Girder

$I_{lg} = \sum I + f \; r^2$

i e the moment of inertia of the lattice girder is equivalent to the sum of the moment of inertia of the individual parts and of the area of the individual parts times the square of their distance to the axis.

If the axis is taken parallel to the basilar membrane and through the center of gravity of the lattice girder a moment of inertia of about 1 000 000 units results which is about 35 times more than the moment of inertia of the tectorial membrane. Actually the difference is more pronounced because the connective tissue on the lower side of the basilar membrane and other cells on top of the basilar membrane will increase the moment of inertia of the architectural structure

Considering these additional parts the difference in moment of inertia is of the same order as the difference in deflections observed by Békésy under static load (cf formula (?) regarding dependence of deflection on moment of inertia)

C. Frequency selectivity of the ear

The envelope of deflections of the basilar membrane (113 114) on which many present theories of hearing are based shows an extremely flat peak. At a sound intensity of 134 db the ratio of the height of the peak exceeding 50% of the amplitude to the length of this bulge is about 1 in 6 000! This makes it impossible to ascribe the rather delicate tuning of the ear to this envelope. The peak of the basilar membrane exceeding 50 of the relative amplitude covers some octaves. This feature is one of the strongest arguments against place theories of hearing in their present form It may be suggested here that the damping of the basilar membrane is also too big to permit delicate tuning of the instrument, because one has to consider the many attached elements (cf Fig. 5) which possess internal friction

The natural frequency of a resonating membrane is affected by its mass. However it is seen, when studying cross sections of the cochlear partition, that masses (cells of Claudius, cells of Hensen, border cells, connective tissue) are arranged on the basilar membrane in an irregular manner along its length This is not compatible with the observed delicate tuning of the ear Wien (115 116) has objected to the Helmholtz theory of hearing on similar theoretical reasons stating that the damping coefficient of the basilar membrane as demanded by Helmholtz s theory is not compatible with the observed response of the ear after a tone is switched off Therefore, the basilar membrane has to be ruled out as a suitable resonator performing the observed frequency analysis.

The resonance peak of the tectorial membrane is, however much narrower and its

as other inherited differences in the design of the instrument.

The theory is, therefore, in a position to explain this phenomenon on the basis of experimental results.

G. Differences in tuning of the two ears (Diplacusis Binauralis)

The observation that the two ears of one person may show differences in tuning (131 132) has furnished resonance (place) theories with heavy ammunition against telephone (frequency theories. As the auditory neural pathway to the hearing centers in both hemispheres of the brain is interconnected (56, et al.) the phenomenon must be of peripheral origin.

In the light of this theory it is evident that differences in tuning will occur if the natural frequency diagrams of the two ears are not congruent, because there is, e.g. an inherited difference between the two sides, like an asymmetric face. If the oscillating structures, in particular the membrana tectoria, are not the mirror image of each other different signals will be fed by each ear into the higher neural pathways. Pathological deviations in construction between the two ears are to be expected.

H. Intensity sensitivity of ear as function of frequency

The very substantial difference in sensitivity at various frequencies at the absolute threshold of hearing (4 28 133) is obvious when considering the physical behaviour of the structures in the light of this approach to the theory of hearing. The lattice girder incorporating the basilar membrane acts as a counter bearing or partner of the tectoria as regards relative movements, and will show a deflection which increases approximately with the third power of the width of the membrane. The alteration of deflection resulting herefrom will accordingly affect the counterbearing capacity of the basilar membrane and therefore the relative movements, as will be discussed under section k.

Using the width of the basilar membrane as shown in Table II and extrapolating the curve towards the stapes, it is seen that the ratio of width for a place, near to the stapes, to a place near to the helicotrema is about 1 12. As the deflection depends about on the third power of the span, the ratio of deflections of 1 in 1 728 results.

Converting the deflection or amplitude ratio to a logarithmic scale as used for the decibel notation in hearing we get.

$$N_{(db)} = 20 \log a / a_2, \qquad (8)$$

where a and a_2 are the amplitudes now inserting the above ratio of deflections in formula (8), it is seen that a difference in sensitivity of about 65 db results, which is in consonance with actual observations.

This calculation does not allow for a number of minor factors, like arrangement of the organ of Corti which is not located always at the same distance from the center of the basilar membrane.

The dimensions given in Table II show further that the thickness of the basilar membrane and therefore its moment of inertia, as well as that of the other important parts of the architectural structure, change as one moves from the stapes to the helicotrema. Attention is also invited regarding the deformation of the tissues under the force of the knife of the microtome, discussed earlier and to a certain amount of loose play in the basilar membrane towards the apex factors which have to be taken into account as they affect the deflection of the basilar membrane. Certain deviations from the sensitivity difference calculated above are therefore, to be expected.

Further energy will be consumed during transmission, which, together with the observed loosed play will also influence the absolute threshold of hearing, considering that the very small volume of lymph displaced by the footplate of the stirrup at low sound intensities will be more effective near the stapes, where the deflections of the basilar membrane and of the tectorial membrane are smaller

ment can therefore, not be reconciled with the deflection curve of this lattice girder

However the anisotropic mechanical properties of the tectorial membrane with very little coupling in the longitudinal direction (cf Fig 2) are in a position to explain this *property of the* ear because even if for demonstration purpose the tectorial membrane is not considered to be anisotropic its *moment* of inertia is about one fiftieth of that of the lattice girder Under uniformly distributed static loads, which are equal for both structures, the deflection of the tectorial membrane will be about the 10^3 fold of that of the girder depending on the place along the cochlear *partition, i e* on the span and *moment* of inertia at each place This value obtained from this investigation, compares *favourably* with the observations of Békésy (96) In spite of the fact that the last calculation can only be considered as a first approximation (considering the problem of exact evaluation of the deflection of the very intricate lattice-girder which follows a complex curve in space and is of *anisotropic organic material) it illustrates a* further observation in accord with the theory

The observed frequency shift is in agreement with the natural frequencies as shown in Table IV and Fig. 13 as a function of the distance from the stapes, and derived from the results of this investigation

It is very interesting to note when comparing the above mentioned amount of just noticeable *longitudinal shift to the distance of the transducer* segments (cf. Fig 2) measured in the longitudinal direction of the cochlear partition that this shift corresponds to two times the distance of transducer segments

In this connection it is, furthermore, worthwhile noting that in the same middle frequency *range the just noticeable frequency shift* (about $1\ 3 \times 10^{-3}$ cm) corresponds to the distance of two teeth of Huschke. The arrangement of the teeth of Huschke on top of the limbus spiralis (cf. Fig. 5) and the fact that the tectorial membrane is attached *to* these teeth, will enhance the development of distinct segments of resonance of the tectorial membrane (reed-type frequency meter effect) The raison d'être *for* this so far neglected and unexplained detail of design of the instrument is confirmed by the theory advanced here

F Similarities in audiograms of related persons

Present theories cannot explain why there are similarities in audiograms of related persons and differences in others Békésy has shown (124) that dimensional differences in the ducts (scalae) as *well* as changes in *impedance* or in location of source, do not practically affect the place of response of the basilar membrane.

It was found in the course of the experiments that the width of the basilar membrane from the stapes to the helicotrema does not follow the same pattern for the various inner ears investigated but that there are some deviations. Such differences are probably inherited, *reminding of similarities between outer* ears, noses, faces, etc. of related persons and pronounced differences between such parts of non related persons.

It will be shown in a later paragraph that the sensitivity at the absolute threshold of hearing is very much affected if one considers such *observed variations in the width of the basilar* membrane Reverting back to equation (2) viz.

$$f = P\ l^3/a\ E\ I$$

and keeping the load P the constant a Young's modulus E and the moment of inertia I constant, and increasing the width l from 1 0 to 1 1 units, i e. by 10% the deflection will increase by about 35% If the width l of the basilar membrane is *changed by 14 6* % the deflection will be altered by 50 This will correspondingly affect the absolute threshold of hearing because the relative deflection is influenced

Also inherited arrangement of the organ of Corti on the basilar membrane i e nearer or more *distant from the point of maximum* deflection will influence the audiogram, as well

as other inherited differences in the design of the instrument.

The theory is, therefore, in a position to explain this phenomenon on the basis of experimental results.

G. Differences in tuning of the two ears (Diplacusis Binauralis)

The observation that the two ears of one person may show differences in tuning (131 132) has furnished resonance (place) theories with heavy ammunition against telephone (frequency theories. As the auditory neural pathway to the hearing centers in both hemispheres of the brain is interconnected (56 et al.) the phenomenon must be of peripheral origin.

In the light of this theory it is evident that differences in tuning will occur if the natural frequency diagrams of the two ears are not congruent, because there is, e.g. an inherited difference between the two sides, like an asymmetric face. If the oscillating structures, in particular the membrana tectoria, are not the mirror image of each other different signals will be fed by each ear into the higher neural pathways. Pathological deviations in construction between the two ears are to be expected.

H. Intensity sensitivity of ear as function of frequency

The very substantial difference in sensitivity at various frequencies at the absolute threshold of hearing (4, 28, 133) is obvious when considering the physical behaviour of the structures in the light of this approach to the theory of hearing. The lattice girder incorporating the basilar membrane acts as a counter bearing or partner of the tectoria as regards relative movements, and will show a deflection which increases approximately with the third power of the width of the membrane. The alteration of deflection resulting herefrom will accordingly affect the counterbearing capacity of the basilar membrane and therefore the relative movements, as will be discussed under section k.

Using the width of the basilar membrane as shown in Table II and extrapolating the curve towards the stapes, it is seen that the ratio of width for a place, near *to the stapes*, to a place near to the helicotrema is about 1 12. As the deflection depends about on the third power of the span, the ratio of deflections of 1 in 1 728 results.

Converting the deflection or amplitude ratio to a logarithmic scale as used for the decibel notation in hearing we get:

$$N_{db} = 20 \log a_1/a_2, \quad (8)$$

where a and a are the amplitudes now inserting the above ratio of deflections in formula (8) it is seen that a difference in sensitivity of about 65 db results, which is in consonance with actual observations.

This calculation does not allow for a number of minor factors, like arrangement of the organ of Corti which is not located always at the same distance from the center of the basilar membrane

The dimensions given in Table II show further that the thickness of the basilar membrane and therefore its moment of inertia, as well as that of the other important parts of the architectural structure, change as one moves from the stapes to the helicotrema. Attention is also invited regarding the deformation of the tissues under the force of the knife of the microtome, discussed earlier and to a certain amount of loose play in the basilar membrane towards the apex factors which have to be taken into account as they affect the deflection of the basilar membrane Certain deviations from the sensitivity difference calculated above are, *therefore* to be expected.

Further energy will be consumed during transmission, which, together with the observed loosed play will also influence the absolute threshold of hearing, considering that the very small volume of lymph displaced by the footplate of the stirrup at low sound intensities will be more effective near the stapes, where the deflections of the basilar membrane and of the tectorial membrane are smaller

ment can therefore not be reconciled with the deflection curve of this lattice girder

However the anisotropic mechanical properties of the tectorial membrane with very little coupling in the longitudinal direction (cf Fig 2) are in a position to explain this property of the ear because even if for demonstration purpose, the tectorial membrane is not considered to be anisotropic its moment of inertia is about one fiftieth of that of the lattice girder Under uniformly distributed static loads, which are equal for both structures, the deflection of the tectorial membrane will be about the 10^2 fold of that of the girder depending on the place along the cochlear partition i e on the span and moment of inertia at each place This value obtained from this investigation, compares favourably with the observations of Békésy (96) In spite of the fact that the last calculation can only be considered as a first approximation (considering the problem of exact evaluation of the deflection of the very intricate lattice girder which follows a complex curve in space, and is of anisotropic organic material) it illustrates a further observation in accord with the theory

The observed frequency shift is in agreement with the natural frequencies as shown in Table IV and Fig. 13 as a function of the distance from the stapes and derived from the results of this investigation.

It is very interesting to note when comparing the above mentioned amount of just noticeable longitudinal shift to the distance of the transducer segments (cf Fig. 2) measured in the longitudinal direction of the cochlear partition that this shift corresponds to two times the distance of transducer segments

In this connection it is furthermore, worthwhile noting that in the same middle frequency range the just noticeable frequency shift (about 1.3×10^{-3} cm) corresponds to the distance of two teeth of Huschke. The arrangement of the teeth of Huschke on top of the limbus spiralis (cf. Fig. 5) and the fact that the tectorial membrane is attached to these teeth will enhance the development of distinct segments of resonance of the tectorial membrane (reed-type frequency meter effect) The raison d'être for this so far neglected and unexplained detail of design of the instrument is confirmed by the theory advanced here

F Similarities in audiograms of related persons

Present theories cannot explain why there are similarities in audiograms of related persons and differences in others. Békésy has shown (124) that dimensional differences in the ducts (scalae) as well as changes in impedance or in location of source, do not practically affect the place of response of the basilar membrane.

It was found in the course of the experiments that the width of the basilar membrane from the stapes to the helicotrema does not follow the same pattern for the various inner ears investigated but that there are some deviations. Such differences are probably inherited reminding of similarities between outer ears noses faces, etc. of related persons and pronounced differences between such parts of non related persons

It will be shown in a later paragraph that the sensitivity at the absolute threshold of hearing is very much affected if one considers such observed variations in the width of the basilar membrane Reverting back to equation (2) viz.

$$f = P\ l^3/a\ E\ I$$

and keeping the load P the constant a Young's modulus E and the moment of inertia I constant and increasing the width l from 1 0 to 1 1 units, i e. by 10% the deflection will increase by about 35% If the width l of the basilar membrane is changed by 14 6% the deflection will be altered by 50% This will correspondingly affect the absolute threshold of hearing because the relative deflection is influenced

Also inherited arrangement of the organ of Corti on the basilar membrane i e nearer or more distant from the point of maximum deflection will influence the audiogram as well

as other inherited differences in the design of the instrument.

The theory is, therefore, in a position to explain this phenomenon on the basis of experimental results.

G. Differences in tuning of the two ears (Diplacusis Binauralis)

The observation that the two ears of one person may show differences in tuning (131 132) has furnished resonance (place) theories with heavy ammunition against telephone (frequency theories. As the auditory neural pathway to the hearing centers in both hemispheres of the brain is interconnected (56, et al.) the phenomenon must be of peripheral origin.

In the light of this theory it is evident that differences in tuning will occur if the natural frequency diagrams of the two ears are not congruent, because there is, e.g. an inherited difference between the two sides, like an asymmetric face. If the oscillating structures, in particular the membrana tectoria, are not the mirror image of each other different signals will be fed by each ear into the higher neural pathways. Pathological deviations in construction between the two ears are to be expected.

H. Intensity sensitivity of ear as function of frequency

The very substantial difference in sensitivity at various frequencies at the absolute threshold of *hearing* (4 28 133) is obvious when considering the physical behaviour of the structures in the light of this approach to the theory of hearing. The lattice girder incorporating the basilar membrane acts as a counter bearing or partner of the tectoria as regards relative movements, and will show a deflection which increases approximately with the third power of the width of the membrane. The alteration of deflection resulting herefrom will accordingly affect the counterbearing capacity of the basilar membrane and therefore the relative movements, as will be discussed under section K.

Using the width of the basilar membrane as shown in Table II and extrapolating the curve towards the stapes, it is seen that the ratio of width for a place, near to the stapes, to a place near to the helicotrema is about 1 12. As the deflection depends about on the third power of the span, the ratio of deflections of 1 in 1 728 results.

Converting the deflection or amplitude ratio to a logarithmic scale as used for the decibel notation in hearing we get

$$N_{sens} = 20 \log a / a_2, \qquad (8)$$

where a and a_2 are the amplitudes now inserting the above ratio of deflections in formula (8) it is seen that a difference in sensitivity of about 65 db results, which is in consonance with actual observations.

This calculation does not allow for a number of minor factors, like arrangement of the organ of Corti which is not located always at the same distance from the center of the basilar membrane.

The dimensions given in Table II show further that the thickness of the basilar membrane and therefore its moment of inertia, as well as that of the other important parts of the architectural structure, change as one moves from the stapes to the helicotrema. Attention is also invited regarding the deformation of the tissues under the force of the knife of the microtome, discussed earlier and to a certain amount of loose play in the basilar membrane towards the apex factors which have to be taken into account as they affect the deflection of the basilar membrane. Certain deviations from the sensitivity difference calculated above are therefore, to be expected.

Further energy will be consumed during transmission, which, together with the observed loosed play will also influence the absolute threshold of hearing, considering that the very small volume of lymph displaced by the footplate of the stirrup at low sound intensities will be more effective near the stapes, where the deflections of the basilar membrane and of the tectorial membrane are smaller

ment can therefore not be reconciled with the deflection curve of this lattice girder

However the anisotropic mechanical properties of the tectorial membrane with very little coupling in the longitudinal direction (cf Fig. 2) are in a position to explain this property of the ear because, even if for demonstration purpose, the tectorial membrane is not considered to be anisotropic its moment of inertia is about one fiftieth of that of the lattice girder Under uniformly distributed static loads, which are equal for both structures the deflection of the tectorial membrane will be about the 10^2 fold of that of the girder depending on the place along the cochlear partition i e on the span and moment of inertia at each place. This value obtained from this investigation compares favourably with the observations of Békésy (96) In spite of the fact that the last calculation can only be considered as a first approximation (considering the problem of exact evaluation of the deflection of the very intricate lattice-girder which follows a complex curve in space, and is of anisotropic organic material) it illustrates a further observation in accord with the theory

The observed frequency shift is in agreement with the natural frequencies as shown in Table IV and Fig. 13 as a function of the distance from the stapes and derived from the results of this investigation.

It is very interesting to note when comparing the above mentioned amount of just noticeable longitudinal shift to the distance of the transducer segments (cf Fig 2) measured in the longitudinal direction of the cochlear partition that this shift corresponds to two times the distance of transducer segments.

In this connection it is, furthermore, worth while noting that in the same middle frequency range the just noticeable frequency shift (about 1.3×10^{-3} cm) corresponds to the distance of two teeth of Huschke. The arrangement of the teeth of Huschke on top of the limbus spiralis (cf Fig 5), and the fact that the tectorial membrane is attached to these teeth will enhance the development of distinct segments of resonance of the tectorial membrane (reed-type frequency meter effect) The raison d être for this so far neglected and unexplained detail of design of the instrument is confirmed by the theory advanced here

F Similarities in audiograms of related persons

Present theories cannot explain why there are similarities in audiograms of related persons and differences in others Békésy has shown (124) that dimensional differences in the ducts (scalae), as well as changes in impedance or in location of source do not practically affect the place of response of the basilar membrane

It was found in the course of the experiments that the width of the basilar membrane from the stapes to the helicotrema does not follow the same pattern for the various inner ears investigated, but that there are some deviations. Such differences are probably inherited reminding of similarities between outer ears noses, faces, etc. of related persons, and pronounced differences between such parts of non-related persons

It will be shown in a later paragraph that the sensitivity at the absolute threshold of hearing is very much affected if one considers such observed variations in the width of the basilar membrane. Reverting back to equation (2) viz.

$$f = P\ l^3/a\ E\ I$$

and keeping the load P the constant a Young s modulus E and the moment of inertia I constant and increasing the width l from 1 0 to 1 1 units, i e. by 10% the deflection will increase by about 35% If the width l of the basilar membrane is changed by 14 6 % the deflection will be altered by 50% This will correspondingly affect the absolute threshold of hearing because the relative deflection is influenced.

Also inherited arrangement of the organ of Corti on the basilar membrane i.e. nearer or more distant from the point of maximum deflection will influence the audiogram as well

as other inherited differences in the design of the instrument.

The theory is, therefore, in a position to ex plain this phenomenon on the basis of experimental results.

G. Differences in tuning of the two ears (Diplacusis Binauralis)

The observation that the two ears of one per son may show differences in tuning (131 132) has furnished resonance (place) theories with heavy ammunition against telephone (fre quency theories. As the auditory neural pathway to the hearing centers in both hemispheres of the brain is interconnected (56, et al.) the phenomenon must be of peripheral origin.

In the light of this theory it is evident that differences in tuning will occur if the natural frequency diagrams of the two ears are not congruent, because there is, e.g. an inherited difference between the two sides, like an asymmetric face. If the oscillating structures, in particular the membrana tectoria, are not the mirror image of each other different signals will be fed by each ear into the higher neural pathways. Pathological deviations in construction between the two ears are to be expected.

H. Intensity sensitivity of ear as function of frequency

The very substantial difference in sensitivity at various frequencies at the absolute *threshold* of hearing (4 28 133) is obvious when consider ing the physical behaviour of the structures in the light of this approach to the theory of hear ing. The lattice girder incorporating the basilar membrane acts as a counter bearing or partner of the tectoria as regards relative movements, and will show a deflection which increases approximately with the third power of the width of the membrane The alteration of deflection resulting herefrom will accordingly affect the counterbearing capacity of the basilar membrane and therefore the relative movements, as will be discussed under section K.

Using the width of the basilar membrane as shown in Table II and extrapolating the curve towards the stapes, it is seen that the ratio of width for a place, near to the stapes, to a place near to the helicotrema is about 1 12. As the deflection depends about on the third power of the span, the ratio of deflections of 1 in 1 728 results.

Converting the deflectron or amplitude ratio to a logarithmic scale as used for the decibel notation in hearing we get:

$$N_{(db)} = 20 \log a_1/a_n \quad (8)$$

where a and a are the amplitudes now inserting the above ratio of deflections in for mula (8) it is seen that a difference in sensitivity of about 65 db results, which is in consonance with actual observations.

This calculation does not allow for a number of minor factors, like arrangement of the organ of Corti which is not located always at the same distance from the center of the basilar membrane.

The dimensions given in Table II show further that the thickness of the basilar membrane and therefore its moment of inertia as well as that of the other important parts of the architectural structure change as one moves from the stapes to the helicotrema. Attention is also invited regarding the deformation of the tissues under the force of the knife of the microtome, discussed earlier and to a certain amount of loose play in the basilar membrane towards the apex, factors which have to be taken into account as they affect the deflection of the basilar membrane. Certain deviations from the sensitivity difference calculated above are, therefore, to be expected.

Further energy will be consumed during transmission, which, together with the observed loosed play will also influence the absolute threshold of hearing, considering that the very small volume of lymph displaced by the footplate of the stirrup at low sound intensities will be more effective near the stapes, where the deflections of the basilar membrane and of the tectorial membrane are smaller

than at the apical side of the cochlear partition.

I Influence of age on the upper frequency limit

Equation (6) for the natural frequency of the architectural structure shows, that a decrease of Young s modulus will lower the frequency of the system It has been shown for some tissues of the body (134) that Young s modulus decreases considerably with advancing age Therefore, the tectorial membrane will be affected and the upper frequency limit will be reduced

It is to be expected that ageing of other parts of the system in particular of those responsible for the generation and conduction of the electric signals will enhance the effect.

K. *Influence of age on the sensitivity of the ear*

The reduction of sensitivity of the ear with advancing age was, so far mostly attributed to reduced efficiency of transmission of energy e g. to otosclerosis and/or to a hitherto obscure deterioration of the neural part including transducers

In the light of this theory it is, however evident that even in the absence of otosclerosis or neural deterioration the sensitivity will be reduced As Young s modulus of the basilar membrane and of the lattice-girder reinforcing it will be affected by the process of ageing, its support to the architectural structures will be reduced and the amplitudes of the basilar membrane will increase Thereby the relative displacement of the membrana tectoria and of the cuticular plate at the top of the hair cells against their lower end is reduced. A similar decrease in Young s modulus applies to the membrana reticularis und to the phalangeal cells, which support the upper and lower side of the transducers. This means that the intensity of a tone, required to cause a sensation at the absolute threshold of hearing must increase more and more with advancing age

L. Effects of a localized lesion of the basilar membrane

It has been pointed out that a localized lesion of the basilar membrane should not change the hydrodynamic conditions or the envelope of the amplitudes of the basilar membrane, or eddies, or shearing forces—all of which have been advanced to explain the properties of the ear at some time—in such a way that there is no tonal sensation for the particular frequency range, if stimulation due to such causes would take place

However adopting the approach suggested here, it is seen that at such places of lesion the base of the structure fails and will follow the oscillations of the membrana tectoria, exercising little or no resistance which means that the relative displacement will be greatly diminished and very small or insufficient strain in the transducers will result

M *Proof that the amplitudes of the membrana tectoria are sufficient to cause a sensation*

When trying to explain the auditory sensations with the help of the envelope of deflections of the basilar membrane or of the cochlear partition as a whole, as done so far the absolute amount of deflection of such structures at the absolute threshold of hearing or even at low sound levels presents a major problem (25 135 139)

For a tone of e g. 200 cps at the absolute threshold of hearing, the amplitude of the basilar membrane is about 10^{-11} cm (25) and for a similar frequency at the threshold of feeling only about 10^{-4} cm (112)

Any theory will therefore, have to explain how the extremely small deflections at the absolute threshold of hearing are sufficient to cause a sensation

The results of studies of the relative stiffness of various membranes of the cochlear partition carried out by Békésy (96) and the results of this investigation prove that there is a pronounced difference in elasticity of up to

second exponential order under static loads, between the tectorial membrane and the lattice girder including the basilar membrane. Békésy's tests, using small magnifications in the microscope and heavy loads, furthermore show a decreasing elasticity towards the stapes, although he mentions only the large variation of elastic properties of the basilar membrane.

As the difference of elasticity between the tectorial and the basilar membrane is of second exponential order under static load, the magnification due to resonance of the tectorial membrane will change this difference to about third exponential order i.e. if the amplitude of the basilar membrane for a 200 cps tone at the absolute threshold is about 10^{-11} cm, equal to 10 μ the amplitude of the membrana tectoria and of the transmitter pins, and, therefore, of the diaphragm closing the top of the transducers, will be about 10 μ The relative displacement, i.e. the elongation or compression of the hair-cells will, therefore, be about 10^{-} μ as the amount to be deducted (10^{-7} μ) can be disregarded.

In this approach, the detailed behaviour of the structure, like the compensation due to compression of the phalangeal cells, sideways deflection of the transducers, particularly towards the apex where they are longer has been simplified for the sake of a first approximation, and as the design of the system suggests that such influences are of secondary importance.

As the compressibility of the cytoplasm in the transducers is extremely small (cf. bulk modulus for liquids), the shape of the transducers will change and their outer membrane as well as the small and large nerve endings will be subjected to strain.

Strain on the transducers due to an upward deflection of the tectorial membrane will be considered first. As the total relative deflection at given conditions is about 10^{-4} μ (assuming an effective length of transducer wall acting on a nerve ending of 10 μ) the maximum axial elongation which will approximately influence a single terminal area of one nerve fiber (effective portion of transducers length over which nerve endings are to be found) is about 4×10^{-8} μ

Considering compression of transducers now if the volume of one transducer which remains constant, is V and its length before and after compression is l_0 and l_1 (i.e. the length of the tubular transducer is l_0, and l_1 is the length reduced by the stroke of the piston) and the respective diameters of the transducers are d_0 and d_1, it is seen that

$$V = \frac{\pi}{4} d_0^2 \ l_0 = \frac{\pi}{4} d_1^2 \ l_1$$

which results in.

$$d_1 = d \sqrt{\frac{l}{l}}$$

Inserting $d_0 = 7.5$ micron, $l_0 = 25$ micron, and $l_1 = 25 - 10^{-4}$ micron, d_1 will be about 7.50024 μ or the increase in circumference of the transducers

$$\Delta U = \Delta d \ \pi = 0.0000752\,\mu.$$

Considering the circumferential elongation of an effective length of 10μ as above, the standard elongation will be about $3.2 \times 10^{-}$ μ. It is seen that the values for compression and elongation are rather similar as are the recorded corresponding amplitudes of the aural microphonics.

Now it will be interesting to see what stress may be approximately expected in the macromolecular substance of the transducer wall and of the nerve fiber

At the very small amplitudes discussed here it is assumed that Hooke's law may be applied to obtain an approximate result. Then the strain is

$$\varepsilon = \alpha \ \sigma \qquad (10)$$

in which α is the reciprocal value of Young's modulus *(E)*, and σ is the stress. From

$\alpha = 1/E$, and

$\varepsilon = \Delta l / l = (l - l_0)/l_0$

$$\sigma = (E \ \Delta l)/l_0 \qquad (11)$$

than at the apical side of the cochlear partition.

I Influence of age on the upper frequency limit

Equation (6) for the natural frequency of the architectural structure shows, that a decrease *of Young's modulus will lower the frequency* of the system. It has been shown for some *tissues of the body (134) that Young's modulus* decreases considerably with advancing age. *Therefore the tectorial membrane will be af*fected and the upper frequency limit will be *reduced*

It is to be expected that ageing of other parts of the system in particular of those responsible for the generation and conduction of *the electric signals will* enhance the effect

K. Influence of age on the sensitivity of the ear

The reduction of sensitivity of the ear with advancing age was so far mostly attributed to reduced efficiency of transmission of energy e g to otosclerosis and/or to a hitherto obscure deterioration of the neural part including transducers

In the light of this theory it is, however evident that even in the absence of otosclerosis or neural deterioration the sensitivity will be reduced As Young's modulus of the basilar membrane and of the lattice-girder reinforcing it will be affected by the process of ageing, its support to the architectural structures will be reduced and the amplitudes of the basilar membrane will increase Thereby the relative displacement of the membrana tectoria and of the cuticular plate at the top of the hair cells against their lower end is reduced A similar decrease in Young's modulus applies to the membrana reticularis and to the phalangeal cells, which support the upper and lower side of the transducers This means that the in*tensity of a tone required to cause a sensation* at the absolute threshold of hearing must increase more and more with advancing age.

L. Effects of a localized lesion of the basilar membrane

It has been pointed out that a localized lesion *of the basilar membrane should not change* the hydrodynamic conditions or the envelope *of the amplitudes of the basilar* membrane, or eddies, or shearing forces—all of which have *been advanced to explain the properties of the* ear at some time—in such a way that there *is no tonal sensation for the particular frequen*cy range if stimulation due to such causes *would take place*

However adopting the approach suggested *here, it is seen that at such places of lesion* the base of the structure fails and will follow the oscillations of the membrana tectoria exercising little or no resistance, which means that the relative displacement *will be greatly dimi*nished and very small or insufficient strain in *the transducers will result*

M Proof that the amplitudes of the membrana tectoria are sufficient to cause a sensation

When trying to explain the auditory sensations with the help of the envelope of deflections of the basilar membrane or of the cochlear partition as a whole, as done so far the absolute amount of deflection of such structures at the absolute threshold of hearing or even at low sound levels presents a major problem (25 135 139)

For a tone of e g 200 cps at the absolute threshold of hearing, the amplitude of the basilar membrane is about 10^{-11} cm (25) and for a similar frequency at the threshold of feeling only about 10^{-4} cm (112)

Any theory will therefore, have to explain how the extremely small deflections at the absolute threshold of hearing are sufficient to cause a sensation

The results of studies of the relative stiffness of various membranes of the cochlear partition, carried out *by Békésy (96) and the re*sults of this investigation prove that there *is a* pronounced difference *in elasticity of up to*

membrana tectoria at the absolute threshold are only amounting about $10^{-}\ \mu$ as compared to a span of the membrane of about 300μ which gives a ratio of deflection to length of the vibrating member of about 1 in 3×10^{6} or for a 60 db tone only about 1 in $3\ 10^{3}$ Therefore, in the subsequent treatment of the problem only a linear system will be considered.

The complete integral of the above equation is

$$y = Ae^{-\,\,t}\sin(\beta t+\varrho_0)\frac{a}{\sqrt{(q-\omega^2)^2+p^2\omega^2}}\sin(\omega t+\varrho\ )\qquad(13)$$

in which ϱ is to be obtained from the particular solution of the differential equation of forced oscillations, viz.,

$$\tan\varrho = \frac{M}{N},\ \text{in which}\ M = \frac{-p\,a\,\omega}{(q-\omega^2)^2+p^2\omega^2}$$

$$N = \frac{a(q-\omega^2)}{(p-\omega^2)^2+p^2\omega^2}$$

the initial phase being ϱ_0.

The first term of the sum on the right side of (13) (the solution of the homogeneous equation) represents damped oscillations and will diminish with increasing time *(t)* and, therefore, after an interval of time the second term representing forced oscillations will acquire prime importance (cf. 109 150, 151)

Such a combination of transient and forced vibrations may however be expected to produce beats, the frequency of which is the difference between $/2$ and $\beta\ /2\pi$ where β is the frequency of free oscillations of the system, which will be damped much faster the more pronounced the damping of the system is.

Such beats caused by the transient and forced vibration are actually to be observed (109) and speak, therefore, very strongly in favour of the existence of a peripheral oscillating system, and support this theory

It will now be of interest to investigate the amplitude of forced oscillations as function of ω for different values of p Denoting the amplitude of forced vibrations by $D(\omega)$ it will be seen that

$$D(\omega) = \frac{a}{\sqrt{(q-\omega^2)^2+p^2\omega^2}}\qquad(14)$$

For $p = 0$ (no resistance) the frequency of free oscillations of the system will be equal to the natural frequency If $q = \beta_1^2$ the equation will become

$$D(\omega) = \frac{a}{\sqrt{(\beta_1^2-\omega^2)^2+p^2\omega^2}}\qquad(15)$$

or introducing the ratio $\omega/\beta_1 = \lambda$ i.e. the ratio of the frequency of the force to the frequency of free oscillations of the system in order to be able to develop the resonance curve for forced, damped oscillations, the new equation will be

$$D(\omega) = \frac{a}{\beta^2\sqrt{\left(1-\frac{\omega^2}{\beta_1^2}\right)+\frac{p^2\omega^2}{\beta_1^2\beta_1^2}}}\qquad(16)$$

or

$$D(\lambda) = \frac{a}{\beta_1^2\sqrt{(1-\lambda^2)^2+\gamma^2\lambda}}\qquad(17)$$

if γ is the ratio of p to β

The maximum of this function will be reached for that value of λ for which the square of the denominator has a minimum, and the minimum of $\sqrt{(1-\lambda^2)^2+\gamma^2\lambda}$ is reached when

$$\lambda = \sqrt{1-\gamma^2/2}\qquad(18)$$

and when this is equivalent to

$$\gamma\sqrt{1\ \ \gamma^2/4}\qquad(19)$$

Therefore, the maximum amplitude will be

$$D_{max} = \frac{a}{\beta^2\sqrt{1-\gamma^2/4}}\qquad(20)$$

It is now possible to construct the above mentioned graph of the function $D(\lambda)$ in a general way taking a and β_1 as unity for the sake of definiteness.

The curves obtained in this way are reso-

is obtained, from which the stress for unit cross section may be calculated

Values for Young s modulus for transducer wall and nerve fibers thereon are not known and therefore they may be estimated with the help of data for organic materials (140–142) Values for (E) given are 10^5 kg/cm^2 for most woods for forces parallel to the grain, and 2 to 3×10^4 kg/cm^2 for polystyrol and polyvinyl chloride Human sinews possess a tensile strength of 600 kg/cm^2 to 1 200 kg/cm^2 (31 143) comparable to the average value for pine of about 900 kg/cm^2 elm (800 kg/cm^2) or poplar (770 kg/cm^2) (140–142) As however the tissues involved are very delicate, the calculations will not only be based on above values, but on a third alternative with only one tenth of the value for polystyrol

Using the standard axial elongation determined above ($4 \times 10^{-5}\mu = 4 \times 10^{-9}$ cm) for Δl and for l the standard length of $10\mu = 10^{-3}$ cm the following stress (σ in kg/cm^2) for the three values of E stated above is obtained

(a) *wood and sinews*

$\sigma = 10^5 \times 4 \times 10^{-9} \times 10^3 = 0\ 4$ kg/cm^2

(b) *polystyrol*

$\sigma = 2 \times 10^4 \times 4 \times 10^{-9} \times 10^3 = 0\ 08$ kg/cm^2

(c) *One tenth of polystyrol i e one-fiftieth of sinews*

$\sigma = 2 \times 10^3 \times 4 \times 10^{-9} \times 10^3 = 0\ 008$ kg/cm^2

It is evident that even the smallest amount of stress of 8 g/cm^2 will produce a sensation, because a much smaller load applied slowly to skin area of medium sensitivity still produces a sensation. In the case of the cochlear partition *the change of load is very rapid, therefore,* the minimum stress required to produce a sensation will be lower according to observations on human skin sensitivity (cutaneous touch) (144–147) In addition the innervation of transducers is more extensive than that of the skin, and also their environmental conditions *are more favourable for ion migration*

Therefore even when considering factors which lower the efficiency it appears that the amplitudes at the *absolute threshold of hearing* are adequate to cause an auditory sensation, on the basis of the physical performance advanced in this theory

N Masking, critical band of masking and of beats

Before discussing phenomena observed in connection with masking it may be stated that *masking is of peripheral origin,* which is confirmed by the observation that masking does not occur when the masking tone is applied to one ear and the masked to the other one (148 149) The little amount of masking observed under such conditions can be ascribed to a great extent to the transmittance of vibrations around the head (112)

It has been observed that low frequency tones mask high frequency tones effectively whereas the *efficiency is much less* in the opposite case This will now be investigated in the light of this theory which suggests a resonator system and will therefore have to follow the law of mechanical vibrations.

In this system the movement is predominant in one direction (relative displacement of the *tectorial membrane*) *therefore, it may be* treated as having one degree of freedom only

The vibrations of the membrana tectoria are subject to elastic forces within this structure (spring constant) and the resisting forces causing damping, which are the fluid resistance (viscosity) and the internal friction. The equation of forced, damped oscillations has the form

$$\ddot{y} + p\dot{y} + qy = a \sin \omega t \qquad (12)$$

Cases where the vibrating system is linear over a wide range of amplitudes are very rare even if the material exposed to vibrations is not organic. Observations (96) *indicate* however that within most of the range of physiological sound intensities the characteristics of the ear are *nearly linear* which seems reasonable in the light of this theory as the deflections of the

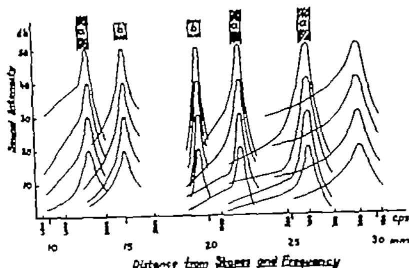

Fig 17 Redrawn masking data, using linear scale for the distance from the stapes as abscissa and showing the frequency reception places along it. The ordinate shows the sound intensity

If available data is re-evaluated in this way resonance curves result. It appears from their shape that damping is small in the central region, which is in agreement with the observation that frequency discrimination of the ear is best there.

Critical bands of masking (*a*) and range of beats (*b*) are shown. They show good agreement with the resonance peaks.

step. Therefore, present theories fail to explain this physical property of the ear

However such sensations, sometimes called quantification seem reasonable at the absolute threshold of hearing, if considered in the light of this theory The transducers are arranged in distinct rows, and the tectorial membrane possesses segmented anisotropic properties. Therefore, a gradual change in intensity or frequency will at a certain level reach the minimum amount of deflection required to switch a further group of transducers in a further row or a different segment on or off, and thereby produce a stepwise change of sensation.

The change in distance between rows, as function of distance from stapes as well as number of transducers energized explains the somewhat bigger steps at the low frequency side of the cochlea. Due to the physical properties of the tectorial membrane, the resonance peak of it becomes wider towards the low frequency range. This explains why the ear is not as sensitive in this range to frequency shifts as compared to the region closer to the stapes.

P Acoustic trauma

Sounds of excessive intensity lead to damage of certain transducers. So far the problem has been mostly treated in a general way but properly stated, three physical phenomena are concerned, for none of which a satisfactory explanation is available if the present theories of hearing are applied. Hereunder each phenomenon will be discussed separately

(1) *Width of Damaged Band of Transducers*

It is obvious that a tone of excessive intensity affects only a narrow segment of the cochlear partition (109). Neither the flat peak of the envelope of displacement of the basilar membrane nor the area affected by eddies are in a position to furnish an explanation.

Considering, however the functioning of the anisotropic tectorial membrane and the resulting resonance curve when stimulated by a tone of excessive intensity on the basis of this theory its pronounced resonance peak explains why only a narrow segment of transducers is affected (cf Fig. 17)

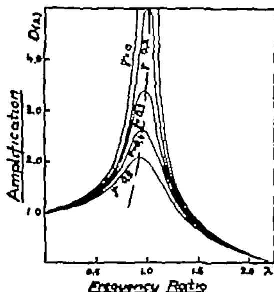

Fig 16 Resonance curves, which show on the ordinate the amplification of vibration due to resonance for various amounts of damping (γ), and on the abscissa the ratio of the frequency of the force to the frequency of the system (λ). The maximum shifts to the left if the damping increases. The amplification is more pronounced for $\lambda < 1$ compared to $\lambda > 1$

nance curves (cf Fig. 16) and are required to determine whether the system under study behaves as demanded in connection with forced, damped oscillations.

It is seen (Fig. 16) that the amplification effect is more pronounced for $\lambda < 1$ which means, returning to the problem of the cochlear partition, on the high frequency side of the force i e on the side of the stapes This, therefore, confirms the observation, according to which masking by a tone of lower frequency is more effective and also that the envelope decreases slower towards the stapes than in the direction of the helicotrema

If a system behaves like a series of resonators as confirmed by above discussions, it seems reasonable that harmonics should occur if the intensity of the tone is sufficiently raised. This is the case (149 152) and furnishes a further confirmation of this theory

It is observed further that the critical band of masking, as well as the band where beats occur are far narrower than the flat peak of deflections of the basilar membrane, and the latter therefore falls also for this reason to furnish an explanation for these observations.

If however the method used mostly when drawing masking diagrams is abandoned, which shows the influence of masking by indicating the sensation level of the primary tone on the abscissa, the threshold shift on the ordinate and the frequency of the secondary tones as parameters, using separate diagrams for each frequency (131 149 152), and the method shown in Fig. 17 is adopted, good agreement between the resonance peak of the tectorial membrane and the critical band of masking is found This means that two rather old observations on masking (149) and on critical bands (127 128 153), confirm this theory and the shape of the resonance curves.

Helmholtz (154) suggested that we hear beats due to imperfect frequency analysing properties of the cochlear mechanism because the two frequency components of the stimulus affect overlapping segments of the basilar membrane.

As the peak of the envelope of the amplitudes of the basilar membrane is very flat, beats should cover a much wider frequency range than actually observed. On the other hand if one assumes that beats are caused by overlapping segments of the resonating tectorial membrane, as suggested by this theory the range where beats may occur becomes much narrower and agrees with observations, as demonstrated in Fig. 17

O Stepwise auditory sensations (quantification)

This phenomenon (4 28 131 155 156) cannot be explained if only the envelope of amplitudes of the basilar membrane or eddies are considered, as both change gradually and not in step-wise fashion. Further any longitudinal shift along the extremely flat peak of the envelope of oscillations of the basilar membrane of the observed amount (cf C and E) does not practically involve a change of amplitude of adjoining areas of the basilar membrane and, therefore, fails to explain a sudden sensational

step. Therefore, present theories fail to explain this physical property of the ear.

However such sensations, sometimes called quantification seem reasonable at the absolute threshold of hearing, if considered in the light of this theory. The transducers are arranged in distinct rows, and the tectorial membrane possesses segmented anisotropic properties. Therefore, a gradual change in intensity or frequency will at a certain level reach the minimum amount of deflection required to switch a further group of transducers in a further row or a different segment on or off, and thereby produce a stepwise change of sensation.

The change in distance between rows, as function of distance from stapes as well as number of transducers energized explains the somewhat bigger steps at the low frequency side of the cochlea. Due to the physical properties of the tectorial membrane, the resonance peak of it becomes wider towards the low frequency range. This explains why the ear is not as sensitive in this range to frequency shifts as compared to the region closer to the stapes.

P. Acoustic trauma

Sounds of excessive intensity lead to damage of certain transducers. So far the problem has been mostly treated in a general way but properly stated, three physical phenomena are concerned, for none of which a satisfactory explanation is available if the present theories of hearing are applied. Hereunder each phenomenon will be discussed separately.

(1) *Width of Damaged Band of Transducers*

It is obvious that a tone of excessive intensity affects only a narrow segment of the cochlear partition (109). Neither the flat peak of the envelope of displacement of the basilar membrane nor the area affected by eddies are in a position to furnish an explanation.

Considering, however the functioning of the anisotropic tectorial membrane and the resulting resonance curve when stimulated by a tone of excessive intensity on the basis of this theory its pronounced resonance peak explains why only a narrow segment of transducers is affected (cf. Fig. 17).

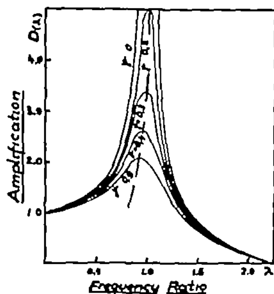

Fig 16 Resonance curves, which show on the ordinate the amplification of vibration due to resonance for various amounts of damping (γ), and on the abscissa the ratio of the frequency of the force to the frequency of the system (λ). The maximum shifts to the left if the damping increases. The amplification is more pronounced for $\lambda < 1$ compared to $\lambda > 1$

nance curves (cf Fig. 16) and are required to determine whether the system under study behaves as demanded in connection with forced damped oscillations.

It is seen (Fig. 16) that the amplification effect is more pronounced for $\lambda < 1$ which means returning to the problem of the cochlear partition, on the high frequency side of the force i.e. on the side of the stapes This therefore confirms the observation according to which masking by a tone of lower frequency is more effective and also that the envelope decreases slower towards the stapes than in the direction of the helicotrema

If a system behaves like a series of resonators, as confirmed by above discussions, it seems reasonable that harmonics should occur if the intensity of the tone is sufficiently raised This is the case (149 152) and furnishes a further confirmation of this theory

It is observed further that the critical band of masking, as well as the band where beats occur are far narrower than the flat peak of deflections of the basilar membrane and *the latter therefore falls also for this reason to furnish an explanation for these observations*

If however the method used mostly when drawing masking diagrams is abandoned, *which shows the influence of masking* by indicating the sensation level of the primary tone on the abscissa the threshold shift on the ordinate and the frequency of the secondary tones as parameters, using separate diagrams for each frequency (131 149 152), *and the* method shown in Fig. 17 is adopted, good agreement between the resonance peak of the *tectorial membrane and the critical band of* masking is found This means that two rather old observations on masking (149) and on critical bands (127 128 153) confirm this theory and the shape of the resonance curves.

Helmholtz (154) suggested that we hear beats due to imperfect frequency analysing properties of the cochlear mechanism because *the two frequency components of the stimulus* affect overlapping segments of the basilar membrane

As the peak of the envelope of the amplitudes of the basilar membrane is very flat, beats should cover a much wider frequency range than actually observed On the other hand if one assumes that beats are caused by overlapping segments of the resonating tectorial membrane, as suggested by this theory the range where beats may occur becomes much narrower and agrees with observations, as demonstrated in Fig. 17

O Stepwise auditory sensations (quantification)

This phenomenon (4 28 131 155 156) can not be explained if only the envelope of amplitudes of the basilar membrane or eddies are considered, as both change gradually and not in step-wise fashion Further any longitudinal shift along the extremely flat peak of the envelope of oscillations of the basilar membrane of the observed amount (cf C and E) does not practically involve a change of amplitude of adjoining areas of the basilar membrane and therefore fails to explain a sudden sensational

The amplitude of forced, damped oscillations is

$$A = \frac{Q}{k\sqrt{\left(1-\frac{\omega^2}{\beta^2}\right) + \frac{c^2\omega^2}{k^2}}} \quad (24)$$

Here Q is the maximum distorting force, k is the spring constant, and c is the coefficient of damping. Rewriting we get:

$$\left(1-\frac{\omega^2}{\beta^2}\right) = \left(\frac{Q}{k\ A}\right) - \left(\frac{c\omega}{k}\right) \quad (25)$$

or

$$\beta_1 = \frac{\omega}{\sqrt{1-\sqrt{\frac{Q^2 - A^2c^2}{k\ A^2}}}} \quad (26)$$

As the efficiency of the transducer system can be regarded to be constant along the cochlear partition, the relative amplitude of the tectorial membrane acting on them remains constant (cf. chapter H)

However the hydrodynamic form of sound energy suffers loss during transmission along the cochlear partition. This is due to the dissipative viscous forces of the liquid, which increases with the length of the path, i.e. towards the places of reception of the low frequencies. Furthermore, the amplitudes of oscillations of the liquid, required to produce a certain effect, also grows towards the apex due to the increased deflection of the basilar membrane there. These viscous forces, therefore, also grow and dissipate more hydraulic energy. Moreover energy is consumed by the cochlear partition due to the internal friction of all parts displaced.

Therefore A remains constant, while Q decreases as given by the formula (26) above: the value of the denominator increases and the angular frequency β will be lowered. This is equivalent to shifting the place of maximum response of the system towards the place of reception of lower frequencies, in agreement with observations.

A similar reduction of the natural frequency of a resonator has been cited by A. Wood (109)

Of course, the actual characteristics will incorporate both effects, and on the basis of the theory advanced here some further small shifts may be expected. For instance, in case the damping of the oscillating system does not change in an identical way for both ears as a function of sound intensity not only shifts in tuning will differ correspondingly for both ears, but also the place of acoustic trauma will be affected.

Q. Stimulation of transducers by flow of lymph

Neubert (43) has suggested, that the hairs of the hair-cells are acted upon by the lymph, which is forced out between the tectorial membrane and the upper side of the organ of Corti, due to differential displacement of the membrane of Reissner against the basilar membrane.

This investigation disproves this theory because there is a connection between the tectorial membrane and the transmitter pins contrary to his assumptions. Furthermore, the tectorial membrane is at its outer edge firmly attached to the organ of Corti. There is, therefore, no slit-nozzle through which liquid may be forced.

As regards the suggestions concerning the generation of sensation due to eddies, many reasons have been given which contradict this possibility. It is suggested to regard eddies, if occurring at all at low or normal sound intensities as side effects they are rather undesirable because they consume valuable energy.

R. Comparison to vestibular apparatus

The cupola of the vestibular apparatus acts like a swinging door which is hinged on the transducers, and is moved when the head turns, due to the inertia of the lymph in a semicircular canal, which has a tendency to remain stationary. These canals are similar from fish to man and direct observations have been

(2) *Transverse Localization of Damage to Transducers*

It has been found that the external transducers are more susceptible to injury due to excessive intensity of a tone, than the inner ones (56 157 158) It is obvious that the outer part of the tectorial membrane is deflected more than the inner side Therefore an excessive strain on the transducers will happen there first

(3) *Longitudinal Localization of Damage to Transducers*

Experiments which expose the ear to high sound intensity resulting in the fatigue of the ear (159 160) or to excessive intensities causing damage (*109 161–165*) produce a phenomenon for which no interpretation has been offered so far

It is found that the place along the cochlear partition which has been affected by the frequency of excessive intensity does not correspond to the place of reception at normal intensities. An upward shift has been observed for about $f > 800$ cps, a downward shift for about $f < 800$ cps.

First the phenomenon of an upward shift will be studied applying the physical basis of this theory

As stated earlier (loc. cit.) the ear mechanism shows linear properties for the normal intensity range Therefore considerations will be based on such behaviour

Reverting to equation (18)

$$\lambda = \sqrt{1 - \gamma^2/2},$$

in which $\lambda = \omega/\beta_1$ and $\gamma = p/\beta_1$ Inserting these expressions we get

$$\omega/\beta_1 = \sqrt{1 - p^2/2\beta_1^2} \tag{21}$$

and solving this equation for β_1 the angular frequency of the oscillator will be

$$\beta_1 = \sqrt{\omega^2 + p^2/2} \tag{22}$$

where p is the resistance

This resistance is normally assumed to be proportional to the velocity at such small amplitudes (110 141) where the velocity depends on the amplitude if the frequency of the o lations is kept constant.

Now it is evident that the amplitude of tectorial membrane and of other oscilla parts of the system will increase when sound intensity is raised. This will be accon nied by an increase in resistance, which res in a shift of the place of maximum respo of the oscillating system In this connect attention is invited to Fig. 16 and it is s that the maxima of the resonance curves s towards the left, in the direction of decreas *λ if γ increases.*

In Table V the natural frequency of ma mum response of the system has been eva ated for a constant frequency of the force (of 1 000 cps The damping (γ) has be varied between 0 and 0 6 As discussed earl $n_f = \omega/2\pi$ and $n_e = \beta_1/2\pi$ Inserting in equ tion (22) one obtains

$$n_e = \sqrt{(2\pi n_f)^2 + p^2}/2\pi, \tag{2$$

in which p is equivalent to $2\pi\beta_1\gamma$ and we g the values as given in Table V

Table V

n_f (cps)	1 000	1 000	1 000	1 000	1 000	1 0
γ[a]	0	0 2	0.3	0.4	0.5	0
p[b]	0	1 250	1 920	2 610	3 310	4 1
n (cps)	1 000	1 01	1 023	1 043	1 067	1 1
Δ cps ( )	0	1.2	2.3	4 3	6.7	

[a] Damping factor [b] Resistance units.

The resistance is however not necessaril proportional to the velocity In hydrodynamic the resistance is assumed to vary with th square of the velocity (110 et al) This wi increase the shift even more Due to the intri cate design of the system one must expect a rather complex behaviour of the characteristic of the system as the sound intensity is raised However the general characteristics will remain the same as discussed above and the theory is, therefore, in a position to explain the observation.

Now the theory will be tested as regards shift of place of damage towards the apex caused by an excessive low frequency sound intensity

The amplitude of forced, damped oscillations is

$$A = \frac{Q}{k\sqrt{\left(1-\frac{\omega^2}{\beta_1^2}\right)^2 + \frac{c^2\omega^2}{k}}} \qquad (24)$$

Here Q is the maximum distorting force, k is the spring constant, and c is the coefficient of damping. Rewriting we get:

$$\left(1-\frac{\omega^2}{\beta_1^2}\right) = \left(\frac{Q}{k \cdot A}\right) - \left(\frac{c\omega}{k}\right) \qquad (25)$$

or

$$\beta_1 = \frac{\omega}{\sqrt{1-\sqrt{\frac{Q^2 - A^2 c_\omega}{k \cdot A^2}}}} \qquad (26)$$

As the efficiency of the transducer system can be regarded to be constant along the cochlear partition, the relative amplitude of the tectorial membrane acting on them remains constant (cf. chapter H).

However the hydrodynamic form of sound energy suffers loss during transmission along the cochlear partition. This is due to the dissipative viscous forces of the liquid, which increases with the length of the path, i.e. towards the places of reception of the low frequencies. Furthermore, the amplitudes of oscillations of the liquid, required to produce a certain effect, also grows towards the apex due to the increased deflection of the basilar membrane there. These viscous forces, therefore, also grow and dissipate more hydraulic energy. Moreover energy is consumed by the cochlear partition due to the internal friction of all parts displaced.

Therefore, A remains constant, while Q decreases as given by the formula (26) above the value of the denominator increases and the angular frequency β_1 will be lowered. This is equivalent to shifting the place of maximum response of the system towards the place of reception of lower frequencies in agreement with observations.

A similar reduction of the natural frequency of a resonator has been cited by A. Wood (109).

Of course, the actual characteristics will incorporate both effects, and on the basis of the theory advanced here some further small shifts may be expected. For instance, in case the damping of the oscillating system does not change in an identical way for both ears as a function of sound intensity not only shifts in tuning will differ correspondingly for both ears, but also the place of acoustic trauma will be affected.

Q. Stimulation of transducers by flow of lymph

Neubert (43) has suggested, that the hairs of the hair-cells are acted upon by the lymph, which is forced out between the tectorial membrane and the upper side of the organ of Corti, due to differential displacement of the membrane of Reissner against the basilar membrane.

This investigation disproves this theory because there is a connection between the tectorial membrane and the transmitter pins contrary to his assumptions. Furthermore, the tectorial membrane is at its outer edge firmly attached to the organ of Corti. There is, therefore, no slit-nozzle through which liquid may be forced.

As regards the suggestions concerning the generation of sensation due to eddies, many reasons have been given which contradict this possibility. It is suggested to regard eddies, if occurring at all at low or normal sound intensities as side effects they are rather undesirable because they consume valuable energy.

R. Comparison to vestibular apparatus

The cupula of the vestibular apparatus acts like a swinging door which is hinged on the transducers, and is moved when the head turns, due to the inertia of the lymph in a semicircular canal, which has a tendency to remain stationary. These canals are similar from fish to man and direct observations have been

(2) *Transverse Localization of Damage to Transducers*

It has been found that the external transducers are more susceptible to injury due to excessive intensity of a *tone than the inner ones (56 157 158)* It is obvious that the outer part of the tectorial membrane is deflected more than the inner side Therefore an excessive strain on the transducers will happen there *first.*

(3) *Longitudinal Localization of Damage to Transducers*

Experiments which expose the ear to high sound intensity resulting in the fatigue of the ear (159 160) or to excessive intensities causing damage (109 161–165) produce a phenomenon for which no interpretation has been offered so far

It is found that the place along the cochlear partition which has been affected by the frequency of excessive intensity does not correspond to the place of reception at normal intensities An upward shift has been observed for about $f > 800$ cps, a downward shift for about $f < 800$ cps.

First the phenomenon of an upward shift will be studied, applying the physical basis of this theory

As stated earlier (loc cit.) the ear mechanism *shows linear properties* for the normal intensity range. Therefore, considerations will be based on such behaviour

Reverting to equation (18)

$$\lambda = \sqrt{1 - \gamma^2/2},$$

In which $\lambda = \omega/\beta_1$ and $\gamma = p/\beta_1$ Inserting these expressions we get

$$\omega/\beta_1 = \sqrt{1 - p^2/2\beta_1^2} \qquad (21)$$

and solving this equation for β_1 the angular frequency of the oscillator will be

$$\beta_1 = \sqrt{\omega^2 + p^2/2} \qquad (22)$$

where p is the resistance

This resistance is normally assumed to be proportional to the velocity at such small amplitudes *(110 141) where the velocity depends on the amplitude if the frequency of the oscillations* is kept constant

Now it is evident that the amplitude of the tectorial membrane and of other oscillating *parts of the system* will increase when the sound intensity is raised. This will be accompanied by an increase in resistance, which results in a shift of the place of maximum response of the oscillating *system In this connection* attention is invited to Fig. 16 and it is seen that the maxima of the resonance curves shift towards the left, in the direction of decreasing λ if γ increases.

In Table V the natural frequency of maximum response of the system has been evaluated for a constant frequency of the force *(n_f)* of 1 000 cps. The damping (γ) has been varied between 0 and 0 6 As discussed earlier $n_f = \omega/2\pi$ and $n = \beta_1/2\pi$ Inserting in equation (22) one obtains

$$n = \sqrt{(2\pi n_f)^2 + p^2/2}/2\pi, \qquad (23)$$

in which p is equivalent to $2\pi\beta_1\gamma$ and we get the values as given in Table V

Table V

n_f (cps)	1 000	1 000	1 000	1 000	1 000	1 000
γ^a	0	0	0.3	0.4	0.5	0 6
p^b	0	1 [illegible]	1 970	610	3 010	4 100
n (cps)	1 000	1 012	1 023	1 043	1 067	1 100
Δ cps ( )	0	[illegible]	2.3	4 3	6.7	10

Damping factor [b] Resistance units.

The resistance is however not necessarily proportional to the velocity In hydrodynamics the resistance is assumed to vary with the square of the velocity (110 et al) This will increase the shift even more. Due to the intricate design of the system one must expect a rather complex behaviour of the characteristics of the system as the sound intensity is raised However the general characteristics will remain the same as discussed above and the theory is, therefore in a position to explain the observation

Now the theory will be tested as regards shift of place of damage towards the apex caused by an excessive low frequency sound intensity

Conclusions

The above discussion shows that this theory is capable of elucidating the physical properties of the ear better than any available theory It is seen that this is possible without any far fetched assumptions, arguments or obscure mechanism. On the contrary the physical behaviour of the cochlear partition as supported by this theory seems to be quite obvious, and each one of the many parts of the system can be assigned a plausible function.

It is seen that the most pronounced short coming of earlier theories is to consider the cochlear partition as one part, in spite of the fact that it contains a great number of precisely built elements. A further shortcoming is not to have obtained sufficient dimensional data to permit complete reproduction of the complex instrument within the cochlear partition. Finally attempts of an understanding of the instrument were faced with considerable difficulties because the instrument was not available intact but considerably distorted.

The approach adopted here, which led to the new theory suggests a considerable scope for further investigations, which can certainly lead to a more detailed understanding of the func tioning of this most complicated instrument of the human body

made on the ampullae in fish The function of the canals has been ascertained by experiments, with models, clinically and theoretically (145 166–178)

It has been established that the cochlea is the phylogenetically younger part of the labyrinthine system and has developed from the vestibular apparatus. There is no reason why nature should have changed the use of the hair cells, which is compression and elongation in the vestibular apparatus when the cochlea was developed It may be of interest that the same design of vestibular apparatus has been used by nature for about 400 million years, and that of the cochlea for only about one quarter of this time This shows that there was apparently little room for further improvement of the mode of action on the transducers, and it is difficult to think that this time tested design should have changed in mammalia. This, therefore also supports the theory advanced here

Conclusions

The above discussion shows that this theory is capable of elucidating the physical properties of the ear better than any available theory It is seen that this is possible without any far fetched assumptions, arguments or obscure mechanism. On the contrary the physical be haviour of the cochlear partition as supported by this theory seems to be quite obvious, and each one of the many parts of the system can be assigned a plausible function.

It is seen that the most pronounced short coming of earlier theories is to consider the cochlear partition as one part, in spite of the fact that it contains a great number of pre cisely built elements. A further shortcoming is not to have obtained sufficient dimensional data to permit complete reproduction of the complex instrument within the cochlear parti- tion. Finally attempts of an understanding of the instrument were faced with considerable difficulties because the instrument was not available intact but considerably distorted.

The approach adopted here, which led to the new theory suggests a considerable scope for further investigations, which can certainly lead to a more detailed understanding of the func tioning of this most complicated instrument of the human body

1 Einleitung

Die Kenntnis der normalen und pathologischen Biochemie der häutigen Strukturen des Innenohres ist aus methodischen Gründen weitgehend auf morphologische (Übersichten: Beck, 1965 Spoendlin, 1966 a Iurato, 1967) und fermenthistochemische Beobachtungen (Vosteen, 1964 et al.) beschränkt. Für mikrochemische Analysen (Naftalin u. Mitarb., 1964 Iurato 1960 1962, Kuhn u. Mitarb 1968) und Stoffwechseluntersuchungen *in vitro* (Chou, 1963 Rauch, 1964 Yanagava, 1964 Mizukoshi u. Mitarb Matschinsky u. Mitarb., 1967) können Zellen und Rezeptoren nicht exakt isoliert werden. Aussichtsreich für die Fragestellungen der Innenohrbiochemie erscheinen daher Verfahren, die an Zellen neben der topischen Zuordnung Messungen im Mikrobereich gestatten.

In der vorliegenden Mitteilung wird über quantitativ-histochemische Untersuchungen am häutigen Innenohr von neugeborenen, reifen und senilen Meerschweinchen berichtet (Tab I). Mit Hilfe von Farbreaktionen wurde photometrisch der relative Eiweiß- und RNA-Gehalt im Cytoplasma fast aller Zellen des Innenohres bestimmt und mit historadiographisch ermittelten Werten des Eiweißumsatzes (Meyer zum Gottesberge, 1961 1965 Plester u. Mitarb., 1962, Koburg, 1961 Koburg u. Mitarb., 1962) verglichen. Die fehlende Parallelität zwischen beiden Größen weist auf eine hohe Intensität der ribosomalen Eiweißsynthese im Corti'schen Organ. Interferenzmikroskopisch wurde am membranösen Labyrinth die Substanzkonzentration als Trockenmasse pro Volumeneinheit und ultraviolett-mikrospektrographisch der Gehalt an aromatischen Aminosäuren im Vergleich zum färberischen Verhalten gegenüber einem anionischen Farbstoff und Gallocyanin-Chromalaun untersucht. Die Meßergebnisse erlauben Rückschlüsse auf die Physiko-Chemie des häutigen Innenohres und dessen Altern.

Verwendete Abkürzungen

2 Material und Methoden

VERSUCHSTIERE, HISTOLOGIE

Verwendet wurden zehn Albino-Meerschweinchen überwiegend weiblichen Geschlechtes aus einem händlereigenen Inzuchtstamm (Ernährung: Mohrrüben, Wasser ad lib.) von 200 bis 300 g Körpergewicht, d. h. an der Grenze zur Geschlechtsreife (Rogers, 1951 Altman 1964). Für interferometrische und uv mikroskopische Untersuchungen am membranösen *Labyrinth (Tab I) wurden zusätzlich fünf neu* geborene (50 bis 80 g, max Lebensalter 4 Tage) und drei senile Tiere (870 g, 670 g und 750 g) benutzt. Das Alter dieser Tiere lag über 5 Jahren als Zeichen der Senilität fanden sich ein *arcus senilis corneae* und typische Krallenveränderungen (Rogers, 1951 Reid u. Mitarb 1953). Innerhalb von 4 Min (Dekapitierung zu beliebigen Tageszeiten im Ätherrausch) wurde ein Drittel der knöchernen Zirkumferenz der Schnecke abgetragen, die einzelnen Schneckenwindungen *zur Fixierung* mittels einer Mikropipette mit 4% Formaldehyd 5% Trichloressigsäure (aa pH 0 6) bei Zimmertemperatur durchspült und das zurechtgeschnittene Felsenbein bei täglichem Wechsel in gleicher Lösung entkalkt. Für cytophotometrische Messungen der Eiweiß- und RNA Konzentration in Zellen von reifen Tieren wurde so kurz wie möglich entkalkt (4–6 Tage) für Untersuchungen am membranösen Labyrinth einheitlich für alle Altersklassen 10 bis 12 Tage lang. Nach Wässern in A dest (pH 5 4–5 8 zweimal 24 Std) wurden die Felsenbeine standardisiert über die aufsteigende Alkoholreihe in Paraffin Paraplast gerichtet eingebettet. Zentrale Schnitte parallel dem Modiolus von rd 7–8 μ Dicke wurden so aufgeklebt, daß ein Kontakt der Schnecke *selbst mit* Eiweiß-Glyzerin vermieden wurde. Für uv mikrospektrographische *Messungen* wurden von zwei Tieren je eine Schnecke und Achillessehne bei gleicher Fixierung bzw Entkalkung nebeneinander eingebettet, um eine möglichst gleichmäßige Schnittdicke zu erreichen.

Die Schnitte wurden *standardisiert in* Xylol entparaffiniert in absolutem Äthanol gespült, kurz luftgetrocknet und für die Interferometrie in Öl vom Brechungsindex $n_{D 20°} = 1\ 40$ (Fa. Cargille New York) und 1 45 (geschliffene Objektträger Deckgläschen von 0 18 mm ± 10% Dicke) für uv mikrospektrographische Messungen in wasserfreiem Glyzerin $n_{D 20°} =$ 1 45 *Deckgläser und Objektträger aus Quarz*) nach Färbungen in Öl von angeglichenem Brechungsindex (*$n_{20°} =$ 1 52–1 53*) eingedeckt.

FÄRBUNGEN

Zum photometrischen Nachweis chemischer Gewebsbestandteile wurden folgende Farbreaktionen verwendet (Tab I)

a) *Gallocyanin-Chromalaun*-Färbung (GC) bei pH 1 64 nach Sandritter u Mitarb (1963 *1966). Zur Kontrolle wurden Schnitte bei* 50 C 2 Std mit 0,5% RNAse (Worthington) in A dest mit *0 2 n NaOH auf pH 7 0 eingestellt* inkubiert und nach kurzem Spülen in A dest. gleichartig gefärbt

Bei Zellen gilt die Reaktion als spezifisch für die Phosphatgruppen der *DNS* die stöchiometrisch erfaßt wird (Sandritter u Mitarb 1966) *und der cytoplasmatischen RNA* (Mundkur 1961 Pakkenberg, 1962 Kiefer u Mitarb., 1966)

Tab. 1. *Übersicht der Messungen am membranösen Labyrinth und Zellen*

	Dichte (g/cm³) (Interferometrie)	Tyrosin-Tryptophan-Konzentration (UV-Mikrospektrographie)	Konzentration von Gesamteiweiß, RNA und Sulfatgruppen (Cytophotometrie nach Färbung mit NGS, GC und nach Millon)
Neugeborene	Basilarmembran	Basilarmembran Tectorialmembran Pfeilerkopf	0
Reife	Basilarmembran Tectorialmembran *Lig. spirale* *Pfeilerkopf*	Basilarmembran Tectorialmembran Pfeilerkopf	1) Basilarmembran Tectorialmembran *Lig. spirale* Pfeilerkopf 2) Cytoplasma von Zellen, vgl. Abb. 1
Senile Versuchstiere	Basilarmembran	*0*	0

Cytophotometrische Meßwerte der Farbstoffkonzentration sind ein relatives Maß für die RNA-Konzentration im Cytoplasma. Im extrazellulären Gewebe reagieren auch *Sulfatgruppen* der Grundsubstanz (Kiefer u. Mitarb. 1966).

b) *Naphtholgelb* S-Färbung (NGS) bei pH 2,7 nach Deitch (1955). Abweichend von der Originalvorschrift wurde 5 Std. lang gefärbt und exakt 5 Min. bei pH 2,7 gewässert.

Bei Zellen werden unspezifisch die basischen Gruppen überwiegend der Hexonbasen Lysin, Arginin und Histidin gefärbt. Die Reaktion hat sich als zuverlässiges Maß für den Gesamtproteingehalt von Zellkern und Cytoplasma erwiesen (Lederer u. Mitarb. 1966, Kraus u. Mitarb. 1968, Übersicht: Deitch, 1966). Am Bindegewebe haben Messungen der Azidophilie aus gleichen Gründen wie bei GC-Färbungen nur orientierenden Charakter (Kelly 1966).

c) *Millon*-Reaktion nach Rasch u. Mitarb. (1960).

Bei 496 nm werden spezifisch die Tyrosin-Gruppen erfaßt. Die Farbstoffkonzentration ist bei Zellen ein Maß für den Gesamtproteingehalt, bei Stützgeweben sind nur Objekte verwandter chemischer Zusammensetzung vergleichbar (Deitch, 1966).

Parallel-Schnitte wurden mit Hämatoxylin-Eosin gefärbt.

GERÄTE UND MESSUNGEN

Das Cytophotometer wurde aus im Handel befindlichen Teilen in einer Modifikation des von Sandritter u. Mitarb. (1959) beschriebenen Typs gebaut. Es besteht aus der Hochleistungslampe (12 V, 100 W), Leuchtfeld- und Meßfeldblende entsprechend 20 µ bzw. 0,7 µ Durchmesser in der Objektebene, achromatischem Kondensor der n. A. von rd. 0,3, Objektiv der n. A. 1,30 (Ölimmersion) bei Justierung nach dem Köhler'schen Prinzip, dem Sekundärelektronenvervielfacher (Typ 1P21, Fa. RCA), Spektralphotometer (Typ PMQ 2, Fa. Zeiss) und dem Netzgerät. Extinktionsmessungen erfolgten nach GC-Färbungen bei 573 nm (T_{max} 19%, HW 10 nm, Präzisionsinterferenz-Filter), nach NGS-Färbungen bei 483 nm (T_{max} 17%, HW 11 nm) und nach Millon-Färbungen bei 496 nm (T_{max} 19%, HW 9 nm).

Für Messungen des Eiweiß- und RNA-Gehaltes von Zellen dienten drei neugeborene und drei reife Tiere mit kurz entkalkten Felsenbeinen mit jeweils 4 bis 5 histologischen Schnitten pro Farbreaktion. Da neben der Farbstoffkonzentration die schwierig zu messende Schnittdicke (Weisbach, 1960, Übersichten: Sandritter 1964, Sandritter u. Mitarb., 1965) in den Extinktionswert eingeht, wurde die Schnittdickenbestimmung wie folgt umgangen.

2 Material und Methoden

VERSUCHSTIERE, HISTOLOGIE

Verwendet wurden zehn Albino-Meerschweinchen überwiegend weiblichen Geschlechtes aus einem händlereigenen Inzuchtstamm (Ernährung: Mohrrüben, Wasser ad lib.) von 200 bis 300 g Körpergewicht d. h. an der Grenze zur *Geschlechtsreife* (Rogers, *1951* Altman, 1964). Für interferometrische und uv mikroskopische Untersuchungen am membranösen Labyrinth (Tab. I) wurden zusätzlich fünf neugeborene (50 bis 80 g, max. Lebensalter 4 Tage) und drei senile Tiere *(870 g, 670 g und* 750 g) benutzt. Das Alter dieser Tiere lag über *5 Jahren als Zeichen der Senilität fanden sich* ein *arcus senilis corneae* und typische Krallenveränderungen (Rogers, 1951 Reid u. Mitarb., 1953). Innerhalb von 4 Min. (Dekapitierung zu beliebigen Tageszeiten im Ätherrausch) wurde ein Drittel der knöchernen Zirkumferenz der Schnecke abgetragen, die einzelnen Schneckenwindungen zur *Fixierung mittels* einer Mikropipette mit 4 % Formaldehyd-5 % Trichloressigsäure (aa pH 0 6) bei Zimmertemperatur durchspült und das zurechtgeschnittene Felsenbein bei täglichem Wechsel in gleicher Lösung entkalkt. Für cytophotometrische Messungen der Eiweiß- und RNA Konzentration *in Zellen von reifen Tieren* wurde so kurz wie möglich entkalkt (4–6 Tage) für Untersuchungen am membranösen Labyrinth einheitlich für alle Altersklassen 10 bis 12 Tage lang. Nach Wässern in A. dest (pH 5 4–5 8 zweimal 24 Std.) wurden die Felsenbeine standardisiert über die aufsteigende Alkoholreihe in Paraffin-Paraplast gerichtet eingebettet. Zentrale Schnitte parallel dem Modiolus von rd. 7–8 μ Dicke wurden so aufgeklebt, daß ein Kontakt der Schnecke selbst mit Eiweiß-Glyzerin *vermieden wurde. Für uv-mikrospek*trographische Messungen wurden von zwei Tieren je eine Schnecke und Achillessehne bei gleicher Fixierung bzw. Entkalkung nebeneinander eingebettet, um eine möglichst gleichmäßige Schnittdicke zu erreichen.

Die Schnitte wurden standardisiert in Xylol entparaffiniert, in *absolutem Äthanol gespült,* kurz luftgetrocknet und für die Interferometrie in Öl vom Brechungsindex n_{D} = 1 40 (Fa. Cargille New York) und 1 45 (geschliffene Objektträger Deckgläschen von 0 18 mm ± 10 % Dicke) für uv-mikrospektrographische Messungen in wasserfreiem Glyzerin n_{D} = 1 45 Deckgläser und Objektträger aus Quarz) nach Färbungen in Öl von angeglichenem Brechungsindex *(n_D = 1 52–1,53) eingedeckt*

FÄRBUNGEN

Zum photometrischen Nachweis chemischer Gewebsbestandteile wurden *folgende Farbreaktionen verwendet (Tab. I)*:

a) *Gallocyanin-Chromalaun* Färbung (GC) bei pH 1 64 nach Sandritter u. Mitarb. (1963 1966). Zur Kontrolle wurden Schnitte bei 50 C 2 Std. mit 0,5 % RNAse (Worthington) in A. dest. mit 0,2 *n* NaOH auf pH 7 0 eingestellt, *inkubiert und nach kurzem Spülen in A.* dest. gleichartig gefärbt.

Bei Zellen gilt die Reaktion als spezifisch für die Phosphatgruppen der DNS die stöchiometrisch erfaßt *wird (Sandritter u. Mitarb.,* 1966) und der cytoplasmatischen RNA (Mundkur 1961 Pakkenberg, *1962 Kiefer u* Mitarb., 1966)

versal-Mikrospektrographen (Typ UMSP I, Fa. Zeiss) unter folgenden Bedingungen.

Kondensor der n. A. 0,8 abgeblendet auf etwa 0,3 des Objektives 1,25 Meßfeldblende und Leuchtfeldblende von 0,5 μ bzw 8 μ Durchmesser in der Objektebene, Vorschub des Schreibers „20" (Einzelheiten bei Trapp 1966). An Schnecken wurden an 6–8 histologischen Schnitten 160 an Achillessehnen 20 kontinuierliche Absorptionsspektren zwischen 350 und 250 nm aufgenommen, bei 16 verschiedenen Wellenlängen in Extinktionswerte umgerechnet und zur Streulichtkorrektur nach Schramm u. Mitarb. (1944) im doppelt-logarithmischen Raster (Abb. 6) aufgezeichnet. Die Steigung der Streulicht Korrekturlinie ist dabei durch 4–6 Meßwerte im Wellenlängenbereich zwischen 350 und 310 nm gegeben. Es wurden die Relationen innerhalb der einzelnen Windungen bestimmt; zum Vergleich zwischen Ohren neugeborener und reifer Tiere mit Achillessehne wurden sämtliche Extinktionswerte nach Streulichtkorrektur gemittelt. Das Extinktionsmaximum wurde aus den Extinktionskurven abgelesen.

STATISTISCHE SICHERUNG

Die Unterschiede der Mittelwerte aller Messungen wurden statistisch nach dem *t* Test (Student, 1908) unter der Annahme einer Normalverteilung auch für interferometrische Dichtewerte geprüft. Als Grenzwert der Wahrscheinlichkeit wurde ein P Wert von 0,05 angenommen. Zur Berechnung wurden die Dichtewerte in g/cm bei UV-Messungen sowohl Einzelmessungen (Extinktionswerte) wie auch die in Prozent ausgedrückten Relationen innerhalb der Schneckenwindungen, bei cytophotometrischen Messungen der Farbstoffkonzentration nur die Relationen innerhalb der Windungsquerschnitte verwendet.

Das Gerät wurde vom Direktor des Instituts für Strahlenbiologie der Universität Münster zur Verfügung gestellt. Der Autor ist Herrn Prof. Dr. W. Dittrich auch für Kritik am Manuskript zu Dank verpflichtet.

FEHLERDISKUSSION

Um Meßwerte der relativen Eiweiß- und RNA Konzentration im Cytoplasma von Zellen des Innenohres mit autoradiographischen Bestimmungen des Aminosäure und RNA Stoffwechsels (Meyer zum Gottesberge, 1961 et al.) vergleichen zu können, mußten entkalkte Felsenbeine benutzt werden. Bei kurzer Einwirkung von Formalin-Trichloressigsäure ist der Aktivitätsverlust inkorporierter Aminosäuren für zahlreiche Zelltypen gering und prozentual gleich (Antoni u. Mitarb., 1965 vgl. Ostrowski u. Mitarb., 1961 Lederer u. Mitarb. 1966 Kraus u. Mitarb., 1968 *b*). Auch am Innenohr sind Aktivitätsverluste (Koburg, 1961) und damit Verluste von cytoplasmatischen Proteinen zu vernachlässigen. Wie weit die Entkalkung zu RNA Verlusten führt, ist nicht genau abzugrenzen. ³H-Cytidinaktivitäten werden durch Säuren stärker reduziert (m-RNA? t-RNA? Schneider u. Mitarb. 1963 Übersicht: Schultze 1968) die Relationen der Silberkorndichte bleiben jedoch nach Entkalkung des Hörorganes erhalten (Koburg, 1961) so daß ein prozentual gleichmäßiger RNA Verlust anzunehmen ist.

Für quantitativ-histochemische Untersuchungen am membranösen Labyrinth wurden die Schnecken länger entkalkt, unterschiedlich hohe Substanzverluste einzelner Strukturen sind zu beachten.

Bei cytophotometrischen Messungen im sichtbaren und UV Bereich sind die apparativ bedingten Fehler zu vernachlässigen (rd. 5% Kondensorapertur Streulicht, Blendendurchmesser Schwarzschild-Villiger Effekt, Nicht Linearität, Spannungsschwankungen ausführliche Diskussion. Sandritter 1958, 1964 Sandritter u. Mitarb., 1965).

Als objektbedingte Fehler kommen Lipofuszin-Pigment der Haarzellen (Ishii u. Mitarb., 1967) in Frage. Striaepithelien mit stärkerem Melaningehalt wurden von den Messungen ausgeschlossen. Böttcher'sche Zellen konnten nicht immer sicher von Sulcusepithelien (zu niedrige Extinktionen), Zellen der Reissner'

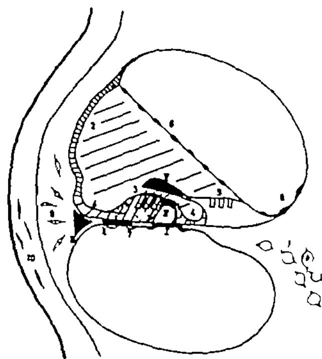

Abb 1 Schematische Darstellung einer Schneckenwindung vom Meerschweinchen mit untersuchten Zellen *1* Ganglienzellen des *Ggl spirale* *2* Epithel der *Stria vascularis*, *3* Corti'sches Organ (innere und äußere Haarzellen *a*, Deiters'sche Zellen *b* Hensen'sche Zellen *c* Böttcher'sche Zellen *4* inneres und äußeres *Sulcusepithel* *5* *Epithel des limbus spiralis*; *6* Zellen der Reissner'schen Membran *7* tympanale Belegzellen *8* Zellen am Boden der Scala vestibuli *9* Fibrozyten des *lig spirale* *10* Osteozyten der Schneckenkapsel. Schwarz Meßpunkte am membranösen Labyrinth. *Pars pectinata* (I) und *tecta* (II) der BM *lig spirale* (III), Pfeilerkopf (IV) und Tectorialmembran (V) Endolymphe schraffiert.

Innerhalb einer Schneckenwindung wurden 6 bis 10 Ganglienzellen und Striaepithelien vom großen und kleinen bzw chromophoben und chromophilen Typ alle Zellen des Corti schen Organes und je 5 übrige Zellen (Abb 1) mit 10 einzelnen Extinktionsbestimmungen pro Zelle untersucht. Die Extinktionswerte vom Cytoplasma wurden für jeden Zelltyp gemittelt, die Mittelwerte in Prozent Werte umgerechnet, wobei die Meßwerte von Ganglienzellen (= 100%) als Bezugswert dienten. Auf diese Weise wurden pro Farbreaktion an 25 bis 30 Schneckenwindungen die mittleren Relationen des cytoplastmatischen Eiweiß- und RNA-Gehaltes bestimmt. Für Messungen der Eiweißkonzentration und GC Färbbarkeit am membranösen Labyrinth wurde gleichartig verfahren.

Für Dichtebestimmungen am Durchlicht Interferenzmikroskop nach Jamin Lebedeff (Typ Standard WL, Fa. Zeiss) wurden folgende Bedingungen eingehalten Kondensor der n. A. etwa 0,3 des Objektives 0 65 Gangunterschiedsbestimmungen erfolgten bei 546,1 nm mit der subjektiven Analysatormethode im homogenen Feld nach Dunkeladaptation (Übersicht: Beneke, 1966) Zur Eliminierung der Schnittdicke (Pehland u Mitarb., 1959) wurde der Gangunterschied zuerst in Öl vom Brechungsindex $n_{D\infty} = 1\,40$ gemessen der Meßpunkt von 2–3 μ Durchmesser in einer Skizze genau markiert, das Präparat in Öl von $n_{D\infty} = 1\,45$ eingedeckt und die Gangunterschiedsbestimmung wiederholt. Die Dichte (c) wurde nach der Formel

$$c = \frac{L_1(n_{m2} - n_e) - L_2(n_{m1} - n_e)}{x(L_1 - L_2)} \qquad (g\,cm^{-3})$$

berechnet wobei L_1 und L_2 die gemessenen Gangunterschiede bzw Phasenverschiebungen n_{m1} und n_{m2} den Brechungsindex der Eindeckmittel n_e den Brechungsindex von A dest. (1 333) und x das spezifische Refraktionsinkrement darstellen (0 0018 vgl Davies, 1958) Von jeweils drei neugeborenen, drei senilen und 4 reifen Tieren wurden 5 bis 6 histologische Schnitte verwendet. Die Meßpunkte sind die gleichen wie nach Bestimmungen der Farbstoffkonzentration (Abb 1) Reifung und Alterung des membranösen Labyrinthes wurden nur an der Basilarmembran verfolgt (Tab I).

Zur Kontrolle der Interferometrie wurden aus 12 Std. fixierten Schnecken Häutchen von *stria vascularis* und BM (Neubert, 1950 Beck, 1964) in gestuft konzentrierten Mischungen von Glucose, NaCl und Glyzerin mit A dest. suspendiert und bei dem Dichtewert abgelesen bei dem das Häutchen in der Schwebe blieb (vgl Bürger 1961) Die Meßergebnisse waren nicht reproduzierbar

Absorptionsmessungen im UV erfolgten an 2 neugeborenen und 2 reifen Tieren (Meßpunkte vgl. Abb

MORPHOLOGIE

Die äußerst empfindlichen Zellen des Corti'schen Organes zeigen bei kurzen Entkalkungszeiten morphologisch weitgehende Integrität (Abb 2) Die Tectorialmembran ist wie nach Entkalkungen üblich von der *lamina reticularis* abgerissen, Zellen und häutiges Labyrinth erscheinen nach NGS und GC Färbungen je nach Farbstoffkonzentration im Hell-Dunkel-Kontrast. Knochengewebe weist nach GC Färbungen im polychromatischen Licht einen violetten Farbton auf (Pseudometachromasie), der am membranösen Labyrinth nur angedeutet ist.

Nach längerer Entkalkung für Untersuchungen am membranösen Labyrinth finden sich an Tectorialmembran und den Zellen des Innenohres interferenzmikroskopisch (Abb. 3) und bei Beobachtung im UV Licht (Abb 4) Auflösungserscheinungen. Doch ist das Stützgewebe von den Zellen gut abzugrenzen.

ERGEBNIS DER MESSUNGEN AN ZELLEN

Als Maß für die relative Eiweiß- und RNA Konzentration im Cytoplasma von Zellen des Innenohres wurde cytophotometrisch die Konzentration von NGS Millon s Reagens und GC bestimmt (Tab. II). Die höchste Färbbarkeit weisen Ganglienzellen des *ggl. spirale* auf es folgen Striaepithelien mit Osteo- und Fibrozyten, während Zellen der Reissner'schen Membran, tympanale Belegzellen und Epithelien des *limbus spiralis* wesentlich niedriger einzuordnen sind. Sehr geringe Farbstoffkonzentrationen finden sich in den Zellen des Corti'schen Organes, wobei Sulcusepithelien, Hensen und Deiters'sche Zellen die niedrigste und innere Haarzellen eine deutlich höhere Farbstoffbindung aufweisen als äußere Haarzellen.

Für die einzelnen Zelltypen stimmen NGS- und Millon-Farbstoffkonzentration recht gut überein (Tab. II, Spalte 1 und 2) unterschiedlich verhält sich der Quotient aus NGS- und GC-Farbstoffgehalt (Spalte 4) Für fast alle untersuchten Zelltypen liegt dieser Wert mit 1 0 bis 1,3 gleich hoch er steigt für Zellen des Corti'schen Organes auf das 1,5 bis 2,5-fache an.

DISKUSSION

Mit quantitativ-histochemischen Methoden wurde bisher nur der Einfluß von Schall auf die RNA und Proteinkonzentration der Ganglienzellen des *ggl. spirale* verfolgt (Hamberger u Mitarb 1945 Hammer 1956 Pakkenberg u. Mitarb., 1964) Vergleichende Untersuchungen an weiteren Zellen des Innenohres stehen aus. Die festgestellten Unterschiede der Farbstoffkonzentration stehen in guter Übereinstimmung mit der Ultrastruktur des membranösen Labyrinthes (Übersichten: Engström, 1965 Spoendlin, 1966 a Iurato 1967) Ganglienzellen und Striaepithelien weisen pro Volumeneinheit im Cytoplasma einen wesentlich höheren Gehalt an Ergastoplasma auf als Sulcusepithelien, und in inneren Haarzellen finden sich relativ mehr cytoplasmatische Organellen als in äußeren Haarzellen.

Ein Vergleich mit autoradiographischen Meßergebnissen des Aminosäure-Stoffwechsels zeigt, daß die Silberkorndichte (Meyer zum Got

schen Membran nicht von deren Interzellular schicht abgegrenzt werden. Bei Osteozyten ist *mit unspezifischer Anfärbung von* Polysaccharid Proteinkomplexen zu rechnen (zu hohe Extinktionen) Die Zahl der Punktmessungen (10) pro Einzelzelle ist bei dem gegebenen Inhomogenitätsgrad (Abb 2) ausreichend. Bei Haarzellen wurden die Meßpunkte gleichmäßig auf infra und supranucleären Bereich verteilt. Nach RNase und GC Färbung waren die Zellen im Cytoplasma ungefärbt an Ganglienzellen und Haarzellen ($n=50$) wurden mittlere Extinktionen von je 0 04 gemessen, d h. der Streulichtfehler liegt für Haarzellen (rd 10%) höher als für Ganglienzellen (rd 5%)

Mit GC kann praktisch selektiv der RNA Gehalt im Cytoplasma bestimmt werden (Kiefer u Mitarb., 1966 1968) eine Beeinflussung der stöchiometrischen Farbstoffbindung durch ribosomale Eiweißkörper ähnlich wie durch Histone bei der DNA von Spermien (Sandritter *u. Mitarb., 1963) ist sehr unwahrscheinlich* da diese Proteine nicht eindeutig zellspezifisch sind (Bielka u Mitarb 1968) Quantitative Untersuchungen an Stützgeweben nach Anfärbung mit GC, NGS und Millon s Reagens haben nur orientierenden Charakter (vgl. *Kelly 1966) Das Absorptionsmaximum* von GC wird durch Mukopolysaccharide verschoben (Pseudometachromasie Sandritter u Mitarb., 1963) in welchem Ausmaß neben Sulfat auch Phosphat und Carboxylgruppen reagieren *ist unbekannt Die Bindung* des anionischen Farbstoffes NGS hängt vom Hydrolysegrad ab (Deitch 1955) An Stützgeweben sind Messungen nach Millon Färbung trotz guter Übereinstimmung mit UV Extinktionen (Rasch u Mitarb 1960) nur bei Geweben verwandter chemischer Zusammensetzung vergleichbar (Deitch 1966)

Die Streulichtkorrektur bei uv mikrospektrographischen Messungen stellt ein Näherungsverfahren dar an Stützgeweben *in situ* liegen keine Erfahrungen vor (Benecke, 1965 vgl *Diskussion*)

Obwohl die Empfindlichkeit der Methode $6\,6 \times 10^{-13}$ g/cm³ erreicht (Bartels, 1966) steigt der hohe Fehler interferometrischer Massenbestimmungen (rd 15% Kraus u Mitarb 1968) bei Dichtemessungen an (Pehland u Mitarb 1959) Dafür dürfte die Objektinhomogenität (Abb 3) und die Anisotropie des membranösen Labyrinthes (Iurato, 1960 1962) verantwortlich sein. Bei jeweils 70 Gangunterschiedsbestimmungen an BM und *Tectorialmembran nach Ausrichten* und im azimutalen Abstand von 90 (Gahm 1962, 1963) fand sich eine mittlere Abweichung von 4 9% die nach dem *mittleren Fehlerfortpflanzungsgesetz* nur zum Teil dem Gesamtfehler addiert werden kann. Ferner stellt das zur Dichteberechnung verwendete Refraktionsinkrement ($x=0\,0018$) einen Näherungswert dar (Benecke, 1966 vgl Buddecke u Mitarb 1967) Mögliche Änderungen während der Reifung oder durch die Fixierung (Hancox u Mitarb 1956 Kraus u Mitarb., 1968 *b*) müssen als Fehlerquelle hingenommen werden.

Mit GC kann praktisch selektiv der RNA Gehalt *im Cytoplasma bestimmt werden (Kiefer u* Mitarb 1966 1968) eine Beeinflussung der stöchiometrischen Farbstoffbindung durch ribosomale Eiweißkörper ähnlich wie durch Histone bei der DNA von Spermien (Sandritter u Mitarb 1963) ist sehr unwahrscheinlich da diese Proteine nicht eindeutig zellspezifisch sind (Bielka u Mitarb 1968) Quantitative Untersuchungen an Stützgeweben nach Anfärbung mit GC, NGS und Millon s Reagens haben nur orientierenden Charakter (vgl. *Kelly 1966)* Das Absorptionsmaximum von GC wird durch Mukopolysaccharide verschoben (*Pseudometachromasie, Sandritter u* Mitarb 1963) In welchem Ausmaß neben Sulfat auch Phosphat und Carboxylgruppen reagieren ist unbekannt. Die Bindung des anionischen Farbstoffes NGS hängt vom Hydrolysegrad ab (Deitch, 1955) An Stützgeweben sind Messungen *nach Millon Färbung trotz gu*ter Übereinstimmung mit UV Extinktionen (Rasch u *Mitarb 1960) nur* bei Geweben verwandter chemischer Zusammensetzung vergleichbar (Deitch 1966)

Die Streulichtkorrektur bei uv mikrospektrographischen Messungen stellt ein Näherungsverfahren dar an Stützgeweben *in situ* liegen keine Erfahrungen vor (Benecke, 1965 vgl Diskussion)

Obwohl die Empfindlichkeit der Methode $6\,6 \times 10^{-14}$ g/cm² erreicht (Bartels, 1966), steigt der hohe Fehler interferometrischer Massenbestimmungen (rd. 15% Kraus u Mitarb 1968) bei Dichtemessungen an (Pehland u *Mitarb 1959) Dafür dürfte die Objektinho*mogenität (Abb 3) und die Anisotropie des membranösen Labyrinthes (Iurato, 1960 1962) verantwortlich sein Bei jeweils 70 Gangunterschiedsbestimmungen an BM und Tectorialmembran nach Ausrichten und im azimutalen Abstand von 90° (Gahm 1962, 1963) fand sich eine mittlere Abweichung von 4 9% die nach dem mittleren Fehlerfortpflanzungsgesetz nur zum Teil dem Gesamtfehler addiert werden kann. Ferner stellt das zur Dichteberechnung verwendete Refraktionsinkrement ($x=0\,0018$) einen Näherungswert dar (Benecke, 1966 vgl Buddecke u Mitarb 1967) Mögliche Änderungen während der Reifung oder durch die Fixierung (Hancox u Mitarb 1956 Kraus u Mitarb., 1968 *b*) müssen *als Fehlerquelle hingenommen werden*

Abb. 3 Corti'sches Organ im Interferenzmikroskop bei 546 nm und maximaler Dunkelstellung der BM. Am rechten Bildrand das sogenannte Schattenbild. 600

noch aussteht (Ficqu u. Mitarb. Niklas u. Mitarb., 1956 Übersicht: Schultze, 1968). Nur Grasso u. Mitarb (1963 1966) berichten über mangelnde Parallelität zwischen Eiweißsynthese und cytoplasmatischer RNA Konzentration während der Reifung von Reticulocyten, die mit Verschiebungen der ribosomalen Aktivität verbunden ist (veränderte Halbwertszeiten der RNA Fraktionen? Fantoni u. Mitarb., 1968 Burka, 1968).

Während noch in der älteren biochemischen Literatur für Bakterien und Zellen eine unspezifische und einheitlich hohe ribosomale Aktivität angenommen wurde (Wilson u Mitarb., 1965 Übersichten: Petermann, 1964 Schweet u. Mitarb., 1966) stehen die an Zellen des Innenohres festgestellten Unterschiede in der Intensität der ribosomalen Peptidsynthese in guter Übereinstimmung mit neueren Erkenntnissen des cytoplasmatischen Eiweißstoffwechsels. Im Verlauf von Wachstum bzw Mitosezyklus (Lucas u. Mitarb., 1964 Salb u. Mitarb 1965 Sykes u Mitarb Enger u. Mitarb 1968 vgl Kiefer u. Mitarb., 1968), während der Embryogenese (Monroy u. Mitarb 1965) Reifung und Alterung (Yamagami u Mitarb 1966) und nach Hungeratrophie (v d. Decken, 1967) schwankt die vom einzelnen Ribosom in der Zeiteinheit synthetisierte Proteinmenge *in vitro* beträchtlich.

Für eine hohe Intensität der ribosomalen Funktion im Corti'schen Organ spricht das Vorkommen der Hensen-Körper in den äußeren Haarzellen, die in ihrer Ultrastruktur (Spoendlin, 1957 1966 a) den sogenannten Nebenkernen entsprechen und als morphologisches Äquivalent einer „intensiven Proteinsynthese gelten (Übersicht: Mölbert, 1968). Ferner stimmt die histochemisch bestimmte Aktivität der Monoaminooxydase (Schätzle u. Mitarb 1967), die allerdings keinen sicheren Indikator der Ribosomenfunktion darstellt, mit der ribosomalen Syntheserate relativ gut überein. Als Ursache für die unterschiedlich intensive Peptidsynthese in den Zellen des Innenohres sind cytoplasmatische Faktoren zu vermuten, da historadiographisch mit Ausnahme von Zellen des *ggl spirale* zwischen RNA Umsatz und Aminosäure-Einbaurate als Maß für die genetische Aktivität Parallelität besteht (Koburg, 1961)

Zu beachten ist die mitochondriale Eiweißsynthese. Bei hohem Cytidinumsatz der mitochondrialen DNS (Chang u. Mitarb 1968) ist wegen der vergleichsweise niedrigen RNA Konzentration (Siebert, 1968 vgl. Tyler 1967)

Abb 2 Histologischer Schnitt eines Corti'schen Organes nach Färbung der Gesamtproteine mit NGS, aufgenommen bei 483 mm, lin. Vergr 900

tesberge 1961 Meyer zum Gottesberge u Mitarb 1965 vgl Koburg u Mitarb., 1962 Plester u Mitarb 1962 Schreiner 1965) nicht mit der cytoplasmatischen RNA Konzentration der Zellen des Innenohres (Tab II Spalte 3 5 und 6) korreliert ist Zellen des Corti schen Organes weisen im Vergleich zu Ganglienzellen einen bis zu siebenfach üb r höhten Eiweißumsatz bezogen auf die Färbbarkeit des Cytoplasma mit GC auf Da mit der GC Färbung die cytoplasmatische RNA Konzentration erfaßt wird die zu 80% oder mehr (Watson 1965 Siebert 1968) aus r RNA besteht, sind die Extinktionswerte ein relatives Maß für die Konzentration von r RNA im Cytoplasma, und der Quotient aus Aminosäure Inkorporation und RNA Konzentration im Cytoplasma bezeichnet die mittlere Aktivität der Ribosomen bei der Eiweißsynthese Nach den Meßergebnissen zu urteilen liegt sie bei Ganglienzellen und Striaepithelien in der gleichen Größenordnung wie bei Fibrozyten tympanalen Belegzellen und Zellen der Reissner schen Membran. Äußere Haarzellen weisen eine intensivere *Proteinsynthese auf als innere Haar*zellen die höchsten Aktivitäten sind dem Sulcusepithel und den Stützzellen der Rezeptoren *zuzuschreiben* Demnach wäre die Intensität der ribosomalen Eiweißsynthese im Cytoplasma eine zellspezifische Größe

In Anbetracht der Fehlermöglichkeiten quantitativ-histochemischer Methoden (vgl. Fehlerdiskussion) ist zu fragen ob Systemfehler für die Meßergebnisse verantwortlich sind Säurebehandlung scheint unwesentlich zu sein An unentkalkten in Kunststoffen eingebetteten Schnecken ist gleichfalls eine fehlende Parallelität zwischen cytoplasmatischer relativer RNA Konzentration und der Silberkorndichte nach Gabe von ³H Leucin (Kraus u. Richrath unpubliziert) festzustellen Fehlende Spezifität bei der Anfärbung der ribosomalen Phosphatgruppen ist unwahrscheinlich, jedoch nicht mit letzter Sicherheit auszuschließen Nicht Linearität zwischen Farbstoffkonzentration und Extinktionswerten ist zumindest für Zellen mit 20% und mehr des RNA-Gehaltes von Ganglienzellen kaum anzunehmen die gemessenen Extinktionen liegen mit 0 2 bis 0 8 im optimalen *Bereich des photometrischen* Nachweises.

Vergleichsmöglichkeiten mit anderen Orga*nen sind nicht gegeben* da eine Korrelation der cytoplasmatischen Basophilie mit den zahlreichen autoradiographischen Messungen des Eiweißstoffwechsels verschiedener Zelltypen

ter der Plasmamembran mit angrenzender Corti-Lymphe ausgerichtet ist. Bekannt ist, daß Intensität und Genauigkeit der Translation in zellfreien Systemen von der Kationenkonzentration (Davies u. Mitarb. Szer u. Mitarb., Friedman u. Mitarb. So u. Mitarb., 1964 Shaeffer u. Mitarb. 1968), dem pH Wert (Grunberg u. Mitarb. 1965), der Temperatur (Szer u. Mitarb. Friedman u. Mitarb. 1964 McCormick u. Mitarb. 1968) und dem Aminosäurespiegel (Baliga u. Mitarb. Sarkar u. Mitarb. 1968) abhängen. Wie weit diese Parameter des „coding environment" am Innenohr von Einfluß sind, ist nicht zu entscheiden, da synoptische vergleichende Untersuchungen an Zellen des Corti'schen Organes und den verschiedenen Lymphen fehlen. Bei den relativ kleinen Kontaktflächen der Zellen des Corti'schen Organes ist auch an das Phänomen der Kontaktinhibition mit Verschiebung der prozentualen Synthese von t m- und r RNA (Rhode u. Mitarb., 1968) zu denken.

Als kausaler Faktor der weitgehend selektiven Ototoxizität der Antibiotica der Streptomycin-Gruppe wurde eine Kumulierung in den Lymphen des Innenohres angenommen (Velikorussova, 1964 Muraveiska, 1965 Stupp u. Mitarb. 1966 Stupp 1969) Doch betragen z. Bsp. die gemessenen Neomycin-Konzentrationen höchstens 20% der maximalen Serumkonzentration (Voldřich, 1965) bei teilweise exzessiv hohen Konzentrationen in Urin und Galle fehlt eine entsprechende Organotropie (Übersichten. Weinstein, 1965 Walter u. Mitarb., 1965) Andererseits sind trotz niedriger Konzentrationen des Antibioticums im Gehirn (André, 1956 Stupp u. Mitarb. 1966 1969) Schädigungen an N. opticus und ZNS relativ häufig. Es liegt nahe, als prädisponierenden Faktor die im Vergleich zu Ganglienzellen hohe ribosomale Syntheserate des Corti'schen Organes anzusehen. Äußere Haarzellen, die gegenüber Streptomycin am empfindlichsten sind (Beck u. Mitarb. 1962 Farkashidy u. Mitarb., 1963 Hawkins u. Mitarb. 1964 Spoendlin, 1966 *b* Übersicht: Engström u. Mitarb., 1965), zeigen eine intensivere Eiweißsynthese

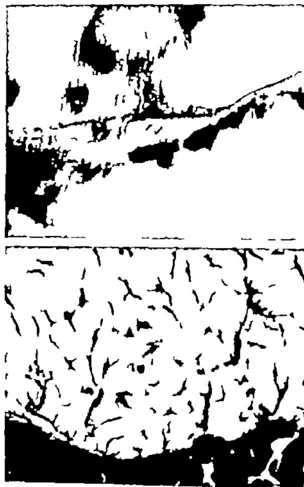

Abb. 4. UV-Mikroskopie bei 270 nm. Oben: *pars recta* der BM innere Haarzelle außerhalb des Focus (1 00). Unten: Achillessehne vom reifen Meerschweinchen, Muskelzellen und Zellkerne von *Fibrozyten* dunkel, Sehnengewebe hell (460).

als innere Haarzellen. Über Streptomycinschäden von *Stützzellen* und Sulcusepithelien, die die höchste Syntheserate aufweisen, wird aber nur vereinzelt berichtet (Reddy u. Mitarb., 1962 Hawkins u. Mitarb., 1964) Sicher sind quantitative Gesichtspunkte allein nicht maßgebend.

Streptomycin blockiert die ribosomale Eiweißsynthese. Es führt zu Ablesefehlern mit Einbau von falschen Aminosäuren (Davies u. Mitarb., 1964). Neben den oben angeführten Faktoren des „coding environment" hängt das Ausmaß des Ablesefehlers auch von der Ba-

Dichtewerte die für alle untersuchten Objekte gleich ist. Die Kurve (Abb 5) ist infolge einer relativen Häufung höherer Meßwerte asymmetrisch. Nach Auftragen im Wahrscheinlichkeitsnetz erweist sich die Verteilung als normal-logarithmisch.

Ultraviolett-mikrospektrographisch bleibt während der Reifung die mittlere, streulichtkorrigierte Extinktion aller Strukturen des membranösen Labyrinthes unverändert (Abb 6) Sie ist mit 0,29 für neugeborene ($n = 70$ $s = 0{,}08$) und reife Tiere gleich hoch ($n = 70$ $s = 0{,}06$). Das Absorptionsmaximum verschiebt sich während des Wachstums von 270 nm bei neugeborenen ($s = 3{,}8$) nach 277 nm bei reifen Tieren ($s = 1{,}9$ $P = 0{,}001$). Gleichzeitig nimmt der Streulichtanteil an der Gesamtabsorption im Absorptionsmaximum ab die Steigung der Korrekturgeraden sinkt von 23 7 ($\mathrm{tg}\,\alpha = 0{,}38$ $s = 12{,}3$) auf 18 8 ($\mathrm{tg}\,\alpha = 0{,}32$ $s = 9{,}0$ $P = 0{,}01$).

An der Achillessehne ist die mittlere Extinktion mit 0,05 ($n = 20$ $s = 0{,}01$ $P = 0{,}001$) wesentlich niedriger Die Steigung der Streulicht Korrekturgeraden liegt bei 12,4 ($\mathrm{tg}\,\alpha = 0{,}22$ $P = 0{,}005$) das Absorptionsmaximum ist nur angedeutet bei 275 nm zu erkennen.

DISKUSSION

Die Dichte morphologischer Strukturen im histologischen Schnitt ist eine Resultante aus dem Verhältnis von Fibrillen zu Grundsubstanz, deren chemischer Zusammensetzung und Hydratationsgrad *in vivo* der von der Molekularstruktur dem Grad der Polymerisation und der Vernetzung der Makromoleküle (Wasserstoffbrückenbindungen, van der Waal'sche Kräfte, elektrostatische Wechselbindungen) und der histologischen Aufarbeitung abhängt. Bei isoliertem Kollagen kann die Dichte je nach Fraktion und Restfeuchtigkeit zwischen 1,34 g/cm³ (Fessler u. Mitarb., 1962) und 1,56 g/cm³ (Kanagy u. Mitarb 1943) betragen, während Keratine (1,3 g/cm³ Finean, 1967), Gelatine (1,27 g/cm³ Hodgman, 1946 1,35 g/cm³ Cowan u Mitarb., 1953) und Fibrinogen (1 39 g/cm³ Scheraga u. Mitarb., 1954) eine niedrigere Substanzkonzentration aufweisen Auch mit Angaben über die Dichte von Zellbestandteilen besteht gute Übereinstimmung (isolierte Zellkerne: 1,3 g/cm³ Behrens, 1956 Ribosomen. 1,6 g/cm³ Sanchez de Jimenez u. Mitarb., 1968 Viren 1,33 g/cm³ Bawden u. Mitarb., 1937 DNS 1 7 g/cm³ Arrhigi u. Mitarb., 1968).

Mit gleicher Methodik wurde an Sehnenfäden der Mitralis eine Substanzkonzentration von 1 15 g/cm³ gemessen (Beneke u. Mitarb., 1967 vgl. Bürger 1961). Demnach muß die BM sehr festes Sehnengewebe darstellen. Von großem Interesse für die Schwingungsgleichung des Innenohres (Impedanz der BM, Schallschnelle, Schallgeschwindigkeit, vgl. Ranke, 1942, 1950 Zwislocki, 1948 Übersicht: Keidel, 1965) wären Dichtewerte der BM *in vivo*

Zt. nichts bekannt Doch wird neuerdings über immunologisch faßbare Organspezifität der ribosomalen Proteine berichtet (Bielka u Mitarb 1968) die möglicher*weise für die Ototoxizität des Streptomycins* verantwortlich ist. Auch ist an Störungen der Membranpermeabilität durch dieses Antibioticum zu denken. Bei *e coli* sind auch sie mit der Streptomycinempfindlichkeit des Eiweißstoffwechsels korreliert (Tamás u Mitarb., 1968)

ERGEBNIS DER MESSUNGEN AM MEMBRANÖSEN LABYRINTH

Interferenzmikroskopisch wurde an histologischen Schnitten die *Substanzkonzentration* (Trockenmasse pro Volumen) von BM Tectorialmembran, *lig spirale* und Pfeilerkopf bestimmt. Die höchste Dichte weist bei reifen Tieren der Pfeilerkopf mit 1 41 g/cm³ (*n* Anzahl der Messungen = 65 Standardabweichung *s* = 0 18) auf es folgen das *lig spirale* (1 35 g/cm³ *n* = 65 *s* = 0 30) und die Basilarmembran mit 1,33 g/cm³ (*n* = 130 *s* = 0 28), während die Tectorialmembran mit 1,20 g/cm³ (*n* = 60 *s* = 0,27) weniger kompakt ist. Statistisch waren die Unterschiede allerdings nicht zu sichern. Die Substanzkonzentration der *pars pectinata* ist im Vergleich zur *pars tecta* der BM bei neugeborenen um 0 27 g/cm³ (*n* = 250 *P* = 0 001) bei senilen Tieren um 0,30 *g/cm³ (n = 190 P = 0 001) höher*

Cytophotometrische Messungen (Tab III) zeigen eine starke Färbbarkeit des Pfeilerkopfes mit NGS Millons Reagens und hohe UV Extinktionen im Vergleich zur BM während an der Tectorialmembran relativ die Farbstoffkonzentration von GC überwiegt.

In den unteren Windungen ist die BM bei neugeborenen um 0 16 g/cm³ (*n* = 240 *P* = 0 02) und bei senilen Tieren um 0 05 g/cm³ (*n* = 240 *P* = 0 2) dichter als in den Windungen der oberen Schneckenhälfte. Gleichzeitig findet sich basal eine relativ *starke Färb*barkeit mit Millons Reagens bei abgeschwächter Färbbarkeit mit GC (Tab IV) UV Extinktionen und Gehalt an NGS sind praktisch gleich

Sehr kompakt ist die BM bei neugeborenen Tieren (1 76 g/cm *n* = 450 *s* = 0,57) Die Dichte nimmt bis zur Geschlechtsreife stark bis auf 1 33 g/cm³ (*n* = 130 *s* = 0,28 *P* = 0 001) ab sie wird während des Alterns geringer reduziert (1 29 g/cm³ *n* = 390 *s* = 0 39 *P* = 0 08)

Auffällig ist die Häufigkeitsverteilung der

Ultraviolett-mikrospektrographisch bleibt während der Reifung die mittlere, streulicht korrigierte Extinktion aller Strukturen des membranösen *Labyrinthes* unverändert (Abb 6). Sie ist mit 0,49 für neugeborene ($n=70$ $s=0{,}08$) und reife Tiere *gleich hoch* ($n=70$ $s=0{,}06$). Das Absorptionsmaximum verschiebt sich während des Wachstums von 270 nm bei neugeborenen ($s=3\ 8$) nach 277 nm bei reifen Tieren ($s=1\ 9$ $P=0{,}001$). Gleichzeitig nimmt der Streulichtanteil an der Gesamtabsorption im Absorptionsmaximum ab, die Steigung der Korrekturgeraden sinkt von 23,7 ($\text{tg}\,\alpha=0{,}38$ $s=12{,}3$) auf 18,8 ($\text{tg}\,\alpha=0{,}32$ $s=9{,}0$ $P=0\ 01$).

An der Achillessehne ist die mittlere Extinktion mit 0,05 ($n=20$ $s=0{,}01$ $P=0{,}001$) wesentlich niedriger *Die Steigung der Streulicht* Korrekturgeraden liegt bei 12,4 ($\text{tg}\,\alpha=0{,}22$ $P=0{,}005$) das Absorptionsmaximum ist nur angedeutet bei 275 nm zu erkennen.

DISKUSSION

Die Dichte morphologischer Strukturen im histologischen Schnitt ist eine Resultante aus dem Verhältnis von Fibrillen zu Grundsubstanz, deren chemischer Zusammensetzung und Hydratationsgrad *in vivo* der von der Molekularstruktur dem Grad der Polymerisation und der Vernetzung der Makromoleküle (Wasserstoffbrückenbindungen, van der Waal'sche Kräfte, elektrostatische Wechselbindungen) und der histologischen Aufarbeitung abhängt. Bei isoliertem Kollagen kann die Dichte je nach Fraktion und Restfeuchtigkeit zwischen 1,34 g/cm³ (Fessler u. Mitarb., 1962) und *1,56* g/cm³ (Kanagy u. Mitarb 1943) betragen, während *Keratine (1,3* g/cm³ *Finean, 1967)* Gelatine (1,27 g/cm Hodgman, 1946 1,35 g/cm³ Cowan u. Mitarb., 1953) und Fibrinogen (1 39 g/cm³ Scheraga u. Mitarb., 1954) eine niedrigere Substanzkonzentration aufweisen Auch mit Angaben über die Dichte von Zellbestandteilen besteht gute Übereinstimmung (isolierte Zellkerne 1,3 g/cm³ Behrens, 1956 Ribosomen: 1 6 g/cm³ Sanchez de Jimenez u. Mitarb., 1968 Viren 1,33 g/cm³ Bawden u. Mitarb., 1937 DNS 1 7 g/cm³ Arrhigi u Mitarb 1968).

Mit gleicher Methodik wurde an Sehnenfäden der Mitralis eine Substanzkonzentration von *1 15* g/cm³ gemessen (Beneke u. Mitarb., 1967 vgl. Bürger 1961). Demnach muß die BM sehr festes Sehnengewebe darstellen. Von großem Interesse für die Schwingungsgleichung des Innenohres (Impedanz der BM, Schallschnelle, Schallgeschwindigkeit, vgl. Ranke, 1942, 1950 Zwislocki, *1948 Übersicht: Keidel, 1965) wären* Dichtewerte der BM *in vivo*

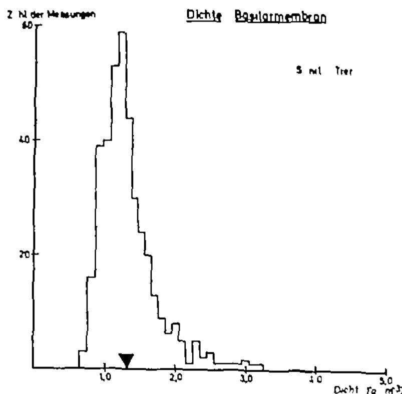

Abb 5 Häufigkeitsverteilung der Dichtewerte von der BM bei senilen Meerschweinchen. Abszisse Dichte in g cm Ordinate: Zahl der Messungen.

Sie können aus unseren Meßwerten nur angenähert unter Annahme eines Wassergehaltes von 70–80 Vol.% und von maximalem Wasserentzug und Schrumpfung bei der histologischen Aufarbeitung mit 1 15–1 23 g/cm³ für neugeborene und 1 07–1 10 g/cm³ für reife Tiere beziffert werden. Dabei handelt es sich wegen wahrscheinlicher Substanzverluste bei der Entkalkung um Mindestwerte

Die hohe Substanzkonzentration der BM im Vergleich zum spezifischen Gewicht von Lymphen bei Säugern (1 02–1 03 g/cm³ v Békésy 1960 vgl Rauch, 1964) ist mit der beobachteten synchronen Schwingungsform von Reissner scher Membran, Endolymphe und BM (v Békésy 1941) schwer zu vereinbaren. Vielleicht wurde die Hydrodynamik des Endolymphschlauches durch die zur stroboskopischen Beobachtung der Reissner schen Membran aufgelagerten Silber und Aluminiumpartikel (Dichte 10,5 bzw 2 7 g/cm³) verändert.

Ein Vergleich der Dichtewerte und von färberischen und uv photometrischen Messungen mit der Ultrastruktur des membranösen Labyrinthes (Spoendlin 1957 Iurato, 1960 1967) zeigt, daß die Trockenmasse pro Volumeneinheit wesentlich von der Packung der Fibrillen abhängt. Die Tectorialmembran weist bei niedriger Dichte und Färbbarkeit der dibasischen (NGS) und aromatischen Aminosäuren (Millon und UV Extinktion) einen relativ hohen Gehalt an reagierenden Sulfat und Carboxyl gruppen auf (GC) was auf ein Überwiegen der Polysaccharid Proteinkomplexe der Grundsubstanz (vgl Schätzle u. Mitarb., 1963 Kuhn u Mitarb., 1968) schließen läßt Auch die niedrigere Dichte der BM in den oberen Windungen steht in guter Übereinstimmung mit der geringeren Anzahl der Fibrillen nach elektronenmikroskopischen Beobachtungen (Iurato, 1962) der Gehalt an Tyrosin (Millon Färbung) ist erniedrigt, die GC Konzentration erhöht.

Am Pfeilerkopf findet sich ferner bei hohen UV Extinktionen eine sehr starke Färbbarkeit mit *Millon s Reagens*. Der Befund spricht für einen hohen prozentualen Gehalt der Filamente der Pfeilerzellen an Tryptophan und besonders Tyrosin (vgl Schätzle u Mitarb., 1966) Da das membranöse Labyrinth bei 275 nm im Mittel fünf bis sechsfach höhere Extinktionen als kollagenes Sehnengewebe auf

weist, ist ein hoher Tyrosin-Tryptophangehalt nicht nur für die Fibrillen des *lig. spirale* (Iurato, 1962) und der Tectorialmembran (Iurato, 1960) sondern des gesamten membranösen Labyrinthes anzunehmen.

Die normal-logarithmische Verteilung der Dichtewerte könnte durch einen methodischen Systemfehler bedingt sein. Die Substanzkonzentration wurde nach einer linearen Proportionalität zwischen Brechungsindex und Dichte (Gladstone-Dale, 1863) errechnet, während Lorentz u. Lorenz (1880) eine exponentielle Relation annehmen. Doch wurde auch bei elektronenmikroskopischen Bestimmungen der Trockenmasse von Mitochondrien (Glas u. Mitarb., 1966) und Spermien (Bahr u. Mitarb., 1964) eine gleichartige Verteilung nachgewiesen, deren biologische Bedeutung zur Zeit unbekannt ist.

Die angedeutet exponentielle Abnahme der Substanzkonzentration während Reifung und Alterung steht im Widerspruch zur Physiko-Chemie der Alterung von Sehnen. Bei reifendem und alterndem kollagenen Stützgewebe kommt es neben einer Reduzierung der Stoffwechselintensität (Hauss u. Mitarb., 1961) und typischen Änderungen in der Molekularstruktur der Polysaccharid-Proteinkomplexe der Grundsubstanz (Buddecke 1958 Kröz u. Mitarb 1967) zu einer relativen Zunahme des Kollagenanteils (Übersicht. Clausen, 1966), indem die kristalline Fraktion ansteigt (Yan Lin u. Mitarb 1968) Bei zunehmendem Vernetzungsgrad resultiert eine verringerte Hydratation, die Dichte steigt an (Bürger 1960, 1961 Übersichten. Sobel u. Mitarb., 1957 Hall, 1968 Bailey 1968)

Wie weit die Dichteabnahme der BM als Zeichen einer „atypischen Alterung" zu deuten ist oder durch besonders hohe Substanzverluste bei der Entkalkung von reifen und senilen Innenohren zu erklären ist, die den normalen Alterungsprozeß maskieren, muß offen bleiben. Auch am Glaskörper nimmt im Alter der Wassergehalt zu bei reduziertem Sediment, Ca- und Eiweißkonzentration (Bembridge u. Mitarb 1951 Bürger u. Mitarb., 1958). Der sichtbaren

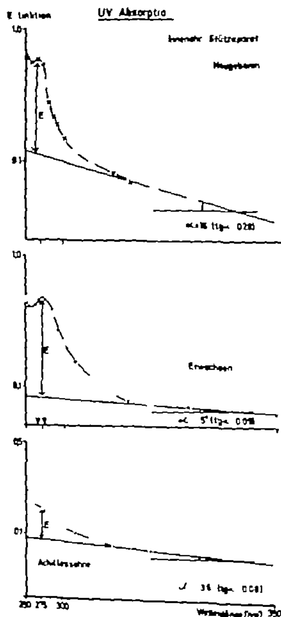

Abb 6 Graphische Darstellung der UV-Extinktionen des membranösen Labyrinthes an neugeborenen (*oben*) und reifen Meerschweinchen (*Mitte*) im Vergleich zur Achillessehne von reifen Tieren (*unten*) im doppeltlogarithmischen Raster Abszisse: Wellenlänge in nm, Ordinate: Extinktion. *E* = konsumptive Extinktion nach Streulichtkorrektur mit der Geraden der Steigung tgα.

Vakuolisierung (Goldmann, 1967 vgl. Hollwich, 1967) entspricht offenbar ein erniedrigter Brechungsindex (Steindorff 1925) Andererseits kann bei der Ratte die zitratlösliche

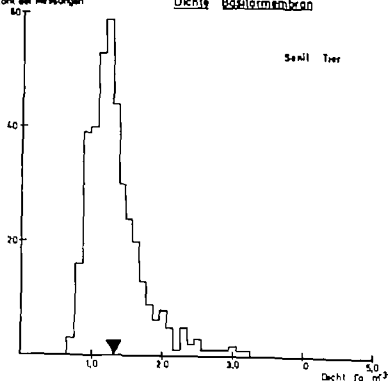

Abb 5 Häufigkeitsverteilung der Dichtewerte von der BM bei *senilen Meerschweinchen*. Abszisse: Dichte in g/cm Ordinate: Zahl der Messungen.

Sie können aus unseren Meßwerten nur angenähert unter Annahme eines Wassergehaltes von 70–80 Vol.% und von maximalem Wasserentzug und Schrumpfung bei der histologischen Aufarbeitung mit 1 15–1 23 g/cm³ für neugeborene und 1 07–1 10 g/cm³ für reife Tiere beziffert werden. Dabei handelt es sich wegen wahrscheinlicher Substanzverluste bei der Entkalkung um Mindestwerte

Die hohe Substanzkonzentration der BM im Vergleich zum spezifischen Gewicht von Lymphen bei Säugern (1 02–1 03 g/cm³ v Békésy 1960 vgl Rauch, 1964) ist mit der beobachteten synchronen Schwingungsform von Reissner'scher Membran, Endolymphe und BM (v Békésy 1941) schwer zu vereinbaren Vielleicht wurde die Hydrodynamik des Endolymphschlauches durch die zur stroboskopischen Beobachtung der Reissner'schen Membran aufgelagerten Silber und Aluminiumpartikel (Dichte 10,5 bzw 2,7 g/cm³) verändert.

Ein Vergleich der Dichtewerte und von färberischen und uv photometrischen Messungen mit der Ultrastruktur des membranösen Labyrinthes (Spoendlin, 1957 Iurato 1960 1967) zeigt, daß die Trockenmasse pro Volumeneinheit wesentlich von der Packung der Fibrillen abhängt. Die Tectorialmembran weist bei niedriger Dichte und Färbbarkeit der dibasischen (NGS) und aromatischen Aminosäuren (Millon und UV Extinktion) einen relativ hohen Gehalt an reagierenden Sulfat und Carboxylgruppen auf (GC) was auf ein Überwiegen der Polysaccharid Proteinkomplexe der Grundsubstanz (vgl Schätzle u Mitarb., 1963 Kuhn u. *Mitarb., 1968) schließen läßt* Auch die niedrigere Dichte der BM in den oberen Windungen steht in guter Übereinstimmung mit der geringeren Anzahl der Fibrillen nach elektronenmikroskopischen Beobachtungen (Iurato 1962) der Gehalt an Tyrosin (Millon Färbung) ist erniedrigt die GC Konzentration erhöht.

Am Pfeilerkopf findet sich ferner bei hohen UV Extinktionen eine sehr starke Färbbarkeit mit Millon s Reagens. Der Befund spricht für einen hohen prozentualen Gehalt der Filamente der Pfeilerzellen an Tryptophan und besonders *Tyrosin* (vgl. *Schätzle u Mitarb* 1966) Da das membranöse Labyrinth bei 275 nm im Mittel fünf bis sechsfach höhere Extinktionen als kollagenes Sehnengewebe auf

4 Zusammenfassung

In histologischen Schnitten der Schnecke vom Meerschweinchen wurden cytophotometrisch nach Naphtholgelb S-, Millon- und Gallocyanin-Chromalaunfärbung die Relationen der cytoplasmatischen Eiweiß- und RNA-Konzentration der Zellen des Innenohres bestimmt. Die höchste Konzentration an cytoplasmatischen Organellen und Ribosomen weisen die Ganglienzellen des *ggl. spirale* (100 %) die niedrigsten die Rezeptoren (20 bis 30 %) und Stützzellen des Corti'schen Organes (10 bis 20 %) auf. Die Meßwerte stimmen mit der Ultrastruktur des Innenohres gut überein. Die Relationen des cytoplasmatischen RNA-Gehaltes weisen weder mit der Eiweißkonzentration noch mit historadiographisch ermittelten Werten der Proteinsynthese (Literatur) Übereinstimmung auf. Der Quotient aus Aminosäure Einbaurate und relativer RNA Konzentration als Maß für die Intensität der ribosomalen Eiweißsynthese ist in den Zellen des Corti schen Organes drei-bis siebenfach hoher als bei Ganglienzellen des *ggl. spirale* Striaepithelien, Fibro- und Osteozyten. Die Meßergebnisse sprechen für eine zellspezifische Intensität der ribosomalen Proteinsynthese. Als Ursache werden cytoplasmatische Faktoren wie Kationenkonzentration, Aminosäurespiegel, pH-Wert und Kontaktinhibition vermutet.

Neben einer Kumulierung von Streptomycin wird die hohe Intensität der ribosomalen Peptidsynthese im Corti'schen Organ als prädisponierend für die Ototoxizität dieses Antibiotikums angesehen. Da äußere Haarzellen gegenüber Streptomycin am empfindlichsten sind, aber die höchste ribosomale Syntheserate den Stützzellen zukommt, werden darüber hinaus spezifische Faktoren im Stoffwechsel der Haarzellen vermutet.

Nach interferometrischen Messungen mit der Zwei-Medien-Methode weist im histologischen Schnitt der Pfeilerkopf die höchste Dichte (1,41 g/cm³) auf; es folgen *lig. spirale* (1,35 g/cm³), Basilar- (1,33 g/cm³) und Tectorialmembran (1,20 g/cm³). Die Basilarmembran ist in den unteren Windungen kompakter als in den oberen Windungen. Die Meßwerte liegen in der gleichen Größenordnung wie die Dichte von chemischen Bestandteilen von Stützgeweben und Strukturen der Zelle. Ein Vergleich mit der Ultrastruktur des membranösen Labyrinthes zeigt, daß die Dichtewerte von der Konzentration von Fibrillen abhängen.

Die Dichte der Basilarmembran weist eine normal-logarithmische Verteilung auf. Sie nimmt von 1,76 g/cm³ bei neugeborenen auf 1,33 g/cm³ bei reifen und 1,29 g/cm³ bei senilen Tieren ab. Die Basilarmembran scheint damit wie der Glaskörper zu altern, während bei reifendem kollagenem Sehnengewebe die Dichte zunimmt. Aus der vergleichsweise hohen Dichte der Basilarmembran errechnen sich unter Annahme eines Wassergehaltes von 70-80 % Dichtewerte *in vivo* von 1,1 bis 1,2 g/cm³, aufgrund deren eine einheitliche Schwingungsform des *ductus cochlearis* als unwahrscheinlich angesehen wird.

Ultraviolett-mikrospektrographisch finden sich am membranösen Labyrinth im Vergleich zur Achillessehne sechsfach höhere Extinktionen. Die relativ starke Färbbarkeit der Tectorialmembran mit Gallocyanin-Chromalaun und des Pfeilerkopfes mit Millon's Reagens bei

Fraktion vom Kollagen der Haut postnatal bis auf dreifache Werte ansteigen (Heikkinen u Mitarb 1968) Neuerdings berichtet Nomura (1970) über den Nachweis von Neutralfetten und Cholesterin in der BM alter Menschen, die möglicherweise als Ursache der Dichteabnahme anzusehen sind

Die uv mikrospektrographischen Befunde lassen sich im einzelnen nicht analysieren Bei Lösungen zeigen Molekülform (Stäbchen oder Kugel) und Teilchengröße (Burberg, 1965) sowie das Verhältnis von Chromophoren zur streuenden Masse (Schauenstein u. Mitarb 1965) in der Extinktion keine eindeutige Abhängigkeit zueinander und zur Wellenlänge Ferner hängt das Extinktionsspektrum neben der *Tyrosin-Tryptophankonzentration* vom Dissoziationsgrad (Peptid-Peptenolbindung, Schauenstein u. Mitarb 1955) in geringerem Ausmaß vom Gehalt an Phenylalanin (Sandritter 1958) und dem UV Dichroismus (Jobst u Mitarb., 1965) ab Auch ist an das Auftreten von ungesättigten Lipiden zu denken (Beneke u Mitarb 1967) Auffällig ist die niedrige Steigung der Streulicht Korrekturgeraden von Bindegewebe im Vergleich zu Lösungen von Nucleoproteiden *in vitro* (Schramm u Mitarb 1944) die mit der hohen Substanzkonzentration von histologischen Schnitten zusammenhängen kann

Eine durch krankhafte Veränderungen der BM verursachte Störung der Hydrodynamik als besondere Form der Innenohrschwerhörigkeit ist denkbar bei der Schwerhörigkeit des Myxödems (vgl. Poulsen, 1966) bei histopathologisch nicht abzuklärenden Innenohr schwerhörigkeiten (Schuknecht u Mitarb., 1965) und als patho-physiologische Teilursache der Altersschwerhörigkeit (Richter 1894 Mayer 1920) bei der Hörverlust und numerische Atrophie des zellulären Apparates nicht immer übereinstimmen (Crowe u Mitarb 1934 Saxén, 1952 Fleischer 1956) Auch bei der Innenohrschwerhörigkeit der Otosklerose kann die Degeneration der Rezeptoren fehlen (Rüedi, 1961) mit Atrophie und cystischer Degeneration des *lig spirale* (Rüedi 1961 Altmann u Mitarb 1966) oder Rupturen der BM (Benitez u Mitarb 1962) verbunden sein. Am Schneckenmodell kann die Wanderwelle in Abhängigkeit der elastischen Eigenschaften der Trennwand bis zum Auftreten von stehenden Wellen oder Resonanz manipuliert werden (v Békésy 1956 Tonndorf 1964) am Innenohr steht der Beweis einer Basilarmembranschwerhörigkeit noch aus.

Über Beziehungen von UV Absorptionsspektrum zur Elastizität von Sehnengewebe ist nichts bekannt. Bei der Alterung von kollagenem Sehnengewebe ist die Dichte mit der Reiß- und Zugfestigkeit korreliert (Rollhäuser 1951 *a b* Hruza u Mitarb 1961 Elden, 1968) Auch am Innenohr entspricht der niedrigeren *Substanzkonzentration* der BM in den oberen Windungen eine Abnahme der Steifigkeit der Trennwand um den Faktor 100 bis 200 (v Békésy 1941 Tonndorf 1964)

Aus der Dichteabnahme im Verlauf der Windungshöhe oder während Reifung und Alterung allein kann allerdings nicht auf eine veränderte Hydrodynamik im Alter geschlossen werden, da die Dicke der BM in höheren Windungen (Übersicht Rauch 1964) und bei der Adoleszenz von *Ratten* zunimmt (Iurato, 1962) während in den Volumelastizitätsmodul von Membranen die Breite in vierter und die Dicke in dritter Potenz eingehen. Offenbar hängen „richtiger" Elastizitätsmodul der BM und altersentsprechendes Hörvermögen von einer sinnvollen Abstimmung von Wachstum und Alterung der Schnecke in den geometrischen Dimensionen einerseits und den physikalisch-chemischen Eigenschaften des membranösen Labyrinthes andererseits ab

Zusammenfassend ist festzustellen, daß die Abnahme der Dichte und des Streulichtanteils an der UV Extinktion mit Verschiebung des Absorptionsmaximums auf *tiefgreifende Strukturwandlungen* der alternden BM schließen lassen, die auf die Hydrodynamik des Innenohres nicht ohne Einfluß sein können Mit den vorliegenden *Befunden allein ist der* histochemische Beweis einer „Basilarmembranschwerhörigkeit" allerdings nicht zu führen

4 Zusammenfassung

An histologischen Schnitten der Schnecke vom Meerschweinchen wurden cytophotometrisch nach Naphtholgelb S- Millon und Gallocyanin-Chromalaunfärbung die Relationen der cytoplasmatischen Eiweiß- und RNA Konzentration der Zellen des Innenohres bestimmt. Die höchste Konzentration an cytoplasmatischen Organellen und Ribosomen weisen die Ganglienzellen des ggl. *spirale* (100 %), die niedrigsten die Rezeptoren (20 bis 30 %) und Stützzellen des Corti'schen Organes (10 bis 20 %) auf. Summary

Quantitative cytochemistry of the inner ear of the young and senile guinea pig

Histological sections of the cochlea of the guinea-pig were stained with naphtol yellow S Millon's reagent and gallocyanin-chrome alum, and the relations of the cytoplasmatic protein and RNA concentration of the cells in the inner ear were determined by cytophotometry The highest concentration of cytoplasmatic organellas and ribosomes is shown to be in ganglion cells of the spiral ganglion (100%), and the lowest concentration is found in the receptors (20–30%) and the supporting cells of the organ of Corti (10–20%). There is a fair degree of correspondence between the test results and the ultrastructure of the inner ear The relative cytoplasmatic RNA content shows no correlation with the protein concentration or with protein synthesis data (see lit.) obtained by autoradiography The quotient of amino acid incorporation rate and RNA concentration as a measure of ribosomal activity is between three and seven times higher in the cells of the organ of Corti than in the ganglion cells of the spiral ganglion, epithelium of the vascular stria, fibro- and osteocytes, suggesting a cell-specific intensity of ribosomal protein synthesis, due to cytoplasmatic factors such as cation concentration, the amino acid level, pH value and contact inhibition.

In addition to an accumulation of streptomycin, the high intensity of ribosomal peptid synthesis in the organ of Corti is considered t be a predisposing factor for the ototoxicity of this antibiotic. Since outer hair cells are most sensitive to streptomycin, but the supporting cells have the highest rate of synthesis, further specific factors in the metabolism of the hair cells are suspected.

According to interferometric measurements with the two-medium method the pillar-heads show the highest density in histological sections (1.41 g/cm³) then follow the spiral ligament (1.35 g/cm³) the basilar (1.33 g/cm³) and the tectorial membrane (1.20 g/cm³). The basilar membrane is more compact in the lower turns than in the upper turns. The test results are within the same order of magnitude as the density of chemical constituents of connective tissues and organellas of the cell. A comparison with the ultrastructure of the membraneous labyrinth shows that the density values depend on the concentration of fibrils.

The density of the basilar membrane shows a normal-logarithmic distribution. It decreases from 1.76 g/cm³ in new-born animals to 1.33 g/cm³ in mature and to 1.29 g/cm³ in senile animals. The basilar membrane thus seems to age like the vitreous body while in maturing collagen tissues there is an increase in density Assuming a water content of about 80% one can calculate density values of the basilar membrane *in vivo* of 1.1 to 1.2 g/cm³ on the basis of which a uniform wave motion of the cochlear duct is considered unlikely

Ultraviolet-microspectrography shows that the average extinction of the membraneous labyrinth is six times as high as in the Achilles tendon. A high percentage of aromatic amino acids in the fibrillary proteins is suggested by the relatively high absorption of the tectorial membrane after staining with gallocyanin-chrome alum and the pillar heads after staining

UV Absorptionen spricht für einen ho-
halt der fibrillären Proteine an aroma
Aminosäuren.
rend der Reifung verschiebt sich das
Absorptionsmaximum des membranö-
yrinthes von 270 nm nach 277 nm und
igung der Streulicht Korrekturgeraden
von 24 auf 19 ab Als mögliche Ur
kommen unterschiedliche Molekül-
Dissoziation und Zusammensetzung
cher Gewebsbestandteile in Frage

Die Befunde beweisen tiefgreifende physiko-chemische Strukturwandlungen am reifenden und alternden membranösen Labyrinth. Morphologische Anhaltspunkte für eine bisher hypothetische Basilarmembranschwerhörigkeit werden aufgeführt und die Meßergebnisse als Anzeichen veränderter Hydrodynamik während Wachstum und Alterung angesehen ohne die Existenz dieses Typs von Innenohrschwerhörigkeit beweisen zu können

Summary

Quantitative cytochemistry of the inner ear of the young and senile guinea pig

Histological sections of the cochlea of the guinea-pig were stained with naphtol yellow S, Millon's reagent and gallocyanin-chrome alum, and the relations of the cytoplasmatic protein and RNA concentration of the cells in the inner ear were determined by cytophotometry The highest concentration of cytoplasmatic organelles and ribosomes is shown to be in ganglion cells of the spiral ganglion (100%), and the lowest concentration is found in the receptors (20–30%) and the supporting cells of the organ of Corti (10–20%). There is a fair degree of correspondence between the test results and the ultrastructure of the inner ear The relative cytoplasmatic RNA content shows no correlation with the protein concentration or with protein synthesis data (see lit.) obtained by historadiography The quotient of amino acid incorporation rate and RNA concentration as a measure of ribosomal activity is between three and seven times higher in the cells of the organ of Corti than in the ganglion cells of the spiral ganglion, epithelium of the vascular stria, fibro- and osteocytes, suggesting a cell-specific intensity of ribosomal protein synthesis, due to cytoplasmatic factors such as cation concentration, the amino acid level, pH-value and contact inhibition.

In addition to an accumulation of streptomycin, the high intensity of ribosomal peptid synthesis in the organ of Corti is considered to be a predisposing factor for the ototoxicity of this antibiotic. Since outer hair cells are most sensitive to streptomycin, but the supporting cells have the highest rate of synthesis, further specific factors in the metabolism of the hair cells are suspected.

According to interferometric measurements with the two-medium method the pillar-heads show the highest density in histological sections (1.41 g/cm³) then follow the spiral ligament (1.35 g/cm³) the basilar (1.33 g/cm³) and the tectorial membrane (1.20 g/cm³). The basilar membrane is more compact in the lower turns than in the upper turns. The test results are within the same order of magnitude as the density of chemical constituents of connective tissues and organelles of the cell. A comparison with the ultrastructure of the membraneous labyrinth shows that the density values depend on the concentration of fibrils.

The density of the basilar membrane shows a normal-logarithmic distribution. It decreases from 1.76 g/cm³ in new-born animals to 1.33 g/cm³ in mature and to 1.29 g/cm³ in senile animals. The basilar membrane thus seems to age like the vitreous body while in maturing collagen tissues there is an increase in density Assuming a water content of about 80% one can calculate density values of the basilar membrane *in vivo* of 1.1 to 1.2 g/cm³ on the basis of which a uniform wave motion of the cochlear duct is considered unlikely

Ultraviolet-microspectrography shows that the average extinction of the membraneous labyrinth is six times as high as in the Achilles tendon. A high percentage of aromatic amino acids in the fibrillary proteins is suggested by the relatively high absorption of the tectorial membrane after staining with gallocyanin-chrome alum and the pillar heads after staining

with Millon's reagent with strong UV absorptions

During maturing the average absorption maximum of the membraneous labyrinth shifts from 270 to 277 nm and the gradient of the correction-line for light scattering drops from 24 to 19 This may be caused by differences in the size of molecules, their dissociation and changed chemical composition of the tissue

The findings prove profound physico-chemical structural changes in the maturing and ageing membraneous labyrinth. They indicate hydrodynamic changes during growth and ageing but cannot prove the existence of a basilar membrane deafness.

Research financed partly by the Consiglio Nazionale delle Ricerche grant No. 04/13 /7/3341 and partly by the Consiglio Nazionale delle Ricerche grant Nos. 1152_77/04 41 69.0 170 115__77 and 70 00992.04 115__77

Part of the research was carried out in the Institute of Biophysics and Electron Microscopy at the University of Dusseldorf

We wish to express our thanks to Miss Carole Davidson for her help in checking the English style of the manuscript

CONTENTS

Introduction

Acetylcholinesterase (AChE) activity was demonstrated in the inner ear for the first time in the perilymph of the pigeon by MARTINI (1941) with the biological method of CHANG and GADDUM (1933), then biologically and by acidity tests by GISSELSSON (1950) in the perilymph and endolymph of the cod pigeon cat and guinea pig.

Later AChE activity was histochemically localized in the cochlea by many authors with the light microscope both in normal and experimental conditions (see Tables 1 and 2). A more detailed localization of AChE in the cochlea was obtained by the electron microscope (see Table 3)

AChE activity was also histochemically demonstrated in the vestibular sensory areas and vestibular nerve with the light and electron microscopes (see Table 4).

It was the aim of the present research to obtain a better understanding of the localization of AChE activity in the inner ear. Preliminary results were reported at the Symposium on Biochemical Mechanisms in Hearing and Deafness held in Minnesota in August 1968 (IURATO et al. 1970) and at the Collegium O.R.L.A.S meeting held in Palermo in September 1970 (IURATO et al. 1971 in press).

Introduction

Acetylcholinesterase (AChE) activity was demonstrated in the inner ear for the first time in the perilymph of the pigeon by MARTINI (1941) with the biological method of CHANG and GADDUM (1933), then biologically and by acidity tests by GISSELSSON (1950) in the perilymph and endolymph of the cod, pigeon, cat and guinea pig.

Later AChE activity was histochemically localized in the cochlea by many authors with the light microscope both in normal and experimental conditions (see Tables 1 and 2). A more detailed localization of AChE in the cochlea was obtained by the electron microscope (see Table 3).

AChE activity was also histochemically demonstrated in the vestibular sensory areas and vestibular nerve with the light and electron microscopes (see Table 4).

It was the aim of the present research to obtain a better understanding of the localization of AChE activity in the inner ear. Preliminary results were reported at the Symposium on Biochemical Mechanisms in Hearing and Deafness held in Minnesota in August 1968 (IURATO et al. 1970) and at the Collegium O.R.L.A.S. meeting held in Palermo in September 1970 (IURATO et al. 1971, in press).

contd Table 1

Authors	Year	Method	Material	Results
Ishii & Balogh	1968	Gomori	cat	P. R. at the outer hair cells decreased towards apex, particularly in outer row. Near apical end all three rows of outer hair cells lacked P. R. Another area of low P. R. at extreme basal end of organ of Corti.
Firbas & Welleschik	1970	Karnovsky	bat	P. R. on efferent nerve fibers and endings and on cochlear ganglion cells. Scarce P. R. in first half of basal turn and in apical turn.

Table 2. *Histochemical AChE localization in the cochlea using light microscopy*
(Experimental animals)

Authors	Year	Method	Material	Experiment	Result
Churchill & Schuknecht; Schuknecht et al.	1959; 1959	Koelle	cat	destruction of hair cell by streptomycin	Positive reaction (P. R.) not appreciably decreased in organ of Corti.
				section of olivo-cochlear bundle (OCB)	P. R. markedly decreased. Presence of AChE activity was first related to efferent OCB fibers.
Conti	1961	Koelle	guinea pig	acoustic trauma	P. R. markedly reduced or negative reaction (N. R.) in organ of Corti, only in turns acoustically stimulated.
Vinnikov & Titov	1958; 1961; 1962; 1963; 1964	Koelle, Friedenwald modified by Gerebtzoff	cat	acoustic trauma	P. R. increased after 30 min exposure, but markedly decreased after longer exposures, in organ of Corti in turns acoustically stimulated.
Rossi & Cortesina	1966	Koelle Friedenwald	guinea pig	destruction of organ of Corti and cochlear ganglion by acoustic trauma + neomycin sulphate	N. R. in cochlear duct. P. R. in intraganglionic spiral bundle.
Mounier-Kuhn & Haguenau	1967	Koelle Friedenwald	guinea pig	acoustic trauma	P. R. decreased in organ of Corti (1st and 2nd turn) after prolonged exposure to high frequency sounds.

Table 1 *Histochemical AChE localization in the cochlea using light microscopy*
(Normal animals)

Authors	Year	Method	Material	Results
CHURCHILL et al. CHURCHILL & SCHUKNECHT SCHUKNECHT et al	1956 1959 1959	KOELLE	cat	Positive reaction (P R) in organ of CORTI on nerve fibers and at base of hair cells. Densest stain in the upper basal turn, progressively decreasing toward basal and apical ends. Negative reaction (N R) in cochlear ganglion cells.
ROSSI	1961	KOELLE FRIEDENWALD	guinea pig	During development P R in organ of Corti and in intraganglionic spiral bundle first appears in basal turn and later extends to others. N R in cochlear ganglion cells except for some early stages of development.
DEL BO & CONTI	1961	KOELLE FRIEDENWALD	guinea pig	P R in cytoplasm of hair cells near nerve endings and along non-myelinated nerve fibers in organ of Corti. During development P R first appears in basal turn
ROSSI & CORTESINA	196.	KOELLE FRIEDENWALD	guinea pig	P R on cochlear efferent fibers in brain stem
VINNIKOV & TITOVA	1958 1961 196. 1963	KOELLE FRIEDENWALD modified by GEREBTZOFF	cat	Intense P R on basal surface of hair cells at sites of their contact with fibers and endings of inner and outer spiral bundles. Marked P R in hairs of inner hair cells throughout the whole length of organ of Corti and in hairs of outer hair cells at the level of basal turn and of lower part of middle turn. Low P R in cytoplasm of hair cells and cochlear ganglion cells.
VINNIKOV et al	1965	KOELLE FRIEDENWALD modified by PEARSE or GEREBTZOFF or HOLMSTEDT	reptilians, birds mammals	Intense P R in nerve endings, in cytoplasm and hairs of hair cells.
NOMURA & SCHUKNECHT	1965	GOMORI	cat, man	P R in intraganglionic spiral bundle and in osseous spiral lamina related to efferent fibers
GACEK et al	1965	GOMORI	cat	P R on efferent cochlear fibers traveling entirely within cochlear nerve toward upper middle and apical turns.
ISHII et al	1967 a	GOMORI	man, monkey cat guinea pig	P R on nerve fibers, not belonging to OCB scattered within cochlear nerve trunk. P R in efferent nerve fibers in osseous spiral lamina on tunnel radial fibers and outer spiral bundles. P R in cochlear ganglion cell of man but not of monkey cat and guinea pig
ISHII et al.	1967 b	GOMORI	squirrel monkey	P R at the inner spiral bundle, 3 outer spiral bundles, upper and lower tunnel radial fibers. N R in cochlear ganglion cells.

Table 4 *Histochemical AChE localization in the vestibular sensory areas*

Authors	Year	Method	Material	Results
DOHLM[illegible] et al.	1958	KOELLE FRIEDENWALD modified by HOLMSTEDT	pigeon	Positive reaction (P R.) at base of the neuroepithelium of cristae ampullares and macula utriculi and at nerve endings between hair cells. Presence of efferent cholinergic fibers.
DOHLMAN	1960	KOELLE FRIEDENWALD modified by HOLMSTEDT	pigeon	High P R. in vestibular sensory areas below neuroepithelium. High butyrylcholinesterase activity in same areas. Could it possibly suggest that butyrylcholine was the chemical mediator for afferent receptor system and acetylcholine belongs to efferent endings
IRELAND & FARKASHIDY	1961	KOELLE FRIEDENWALD	guinea pig	P R. localized at nerve endings and fibers below and between hair cells in ampullae of all three semicircular canals and macula utriculi. Negative reaction (N. R.) when auditory nerve [illegible] sectioned.
ROSSI	1961	KOELLE FRIEDENWALD	guinea pig	N. R. in macula utriculi, macula sacculi and cristae ampullares of semicircular canals during fetal development and in young animals. During development unspecific ChE activity was present; it disappeared before birth at level of maculae utriculi and sacculi and in adult animals at level of cristae ampullares. Constant P R. in cells of vestibular ganglion during development and in adult animals. P R. in nerve fiber bundles in central branch of vestibular nerve.
HILDING & WERSÄLL	196[illegible]	KOELLE FRIEDENWALD modified by HOLMSTEDT applied to EM	guinea pig	Using electron microscope black precipitate was found in the small granulated nerve endings at the bottom of type II hair cell and in nerve endings on outside of nerve chalices of type I cell. Using light microscope after incubation with BW C 51 for demonstrating butyrylcholinesterase diffuse staining of cristae ampullares more intense in planum semilunatum.
ROSSI & CORTESINA	196[illegible]	KOELLE FRIEDENWALD	guinea pig	P R. in fiber bundles in branches of vestibular nerve.
ROSSI et [illegible]	1964	KOELLE FRIEDENWALD	rabbit	N R. throughout efferent vestibular fiber system and at cristae ampullares after arterial injection of diisopropylfluorophosphate (DFP). P R. after restoration in normal conditions.

Table 3 Histochemical AChE localization in the cochlea using electron microscopy

Authors	Year	Method	Material	Results
Wersäll et al Hilding & Wersäll	1961 1962	Koelle Friedenwald modified by Holmstedt applied to EM	guinea pig	Positive reaction (P R.) in inner spiral bundle and under outer hair cells of all rows in basal turn, of first and second row in middle turn and only of first row in apical turn Same localization as that of efferent nerve endings.
Uchizono et al	1967	Karnovsky	man (2 hr post-mortem)	P R on axolemma of myelinated and non-myelinated cochlear nerve fibers in osseous spiral lamina
Kaneko Kaneko & Daly	1968 1968	Karnovsky	guinea pig	P R on upper tunnel radial fibers and efferent nerve endings to outer hair cells, Negative reaction (N R) on lower tunnel radial fibers.
Kaneko & Daly	1969	Karnovsky	guinea pig	P R. on endolymphatic surface of outer hair cells. N R. on surface of supporting cells.

WERSÄLL et al HILDING & WERSÄLL	1961 1962	KOELLE FRIEDENWALD modified by HOLMSTEDT applied to EM	guinea pig	Positive reaction (P R.) in inner spiral bundle and under outer hair cells of all rows in basal turn, of first and second row in middle turn and only of first row in apical turn. Same localization as that of efferent nerve endings.
UCHIZONO et al	1967	KARNOVSKY	man (hr post-mortem)	P R on axolemma of myelinated and non-myelinated cochlear nerve fibers in osseous spiral lamina
KANEKO KANEKO & DALY	1968 1968	KARNOVSKY	guinea pig	P R on upper tunnel radial fibers and efferent nerve endings to outer hair cells. Negative reaction (N R) on lower tunnel radial fibers.
KANEKO & DALY	1969	KARNOVSKY	guinea pig	P R on endolymphatic surface of outer hair cells. N R on surface of supporting cells.

Materials and Methods

Two adult guinea pigs and five adult chinchillas of both sexes were anesthetized with an endoperitoneal injection of sodium pentobarbital (35mg/kg). The inner ear was prefixed *in vivo* by a 10 min perilymphatic perfusion of the fixative at room temperature (IURATO and DE PETRIS, 1967). The animal was sacrificed and immediately after the temporal bones were quickly removed. The bony cochlea was completely opened and the stapes taken away to allow a good penetration of the fixative. The specimens were left for 3 hr at 0°–4°C in the same fixative used for the perfusion.

Fixation was done in 4 formaldehyde obtained from paraformaldehyde (Fluka A. G Bucks, St Gallen) according to KARNOVSKY (1965) or in 3 glutaraldehyde (Biological Grade, Fisher Scientific Co., Fair Lawn, N J) The aldehydes were diluted in the following buffers

0 075 M phosphate buffer prepared according to SORENSEN the buffer contained 0 44 M sucrose

isotonic phosphate buffer prepared according to MILLONIG (1961) the buffer contained one drop of a 1 $CaCl_2$ solution every 10 ml

0 08 0 1 M sodium cacodylate buffer containing one drop of a 1 CaCl solution every 10 ml

During fixation the bony covering of the cochlea was partially removed and the vestibulum opened the cristae ampullares and maculae utriculi and sacculi were identified and partly dissected

After fixation was completed the specimens were placed in the same previously used buffer or in a 0 44 M sucrose for 1 12 hr and the dissection of the cochlea and vestibular sensory areas was continued. Part of the specimens were then transferred into the incubation medium (substrate acetylthiocholine iodide, Hoffmann La Roche & Co Ltd., Basel) prepared according to KARNOVSKY (1964) and kept on ice For specimens incubated *in toto* the period of incubation varied from 20-40 min,

On part of the material the following controls were made

a) Incubation for 40 min in the medium lacking substrate.

b) Pre-incubation at 0°-4°C for 1 hr in 0 44 M sucrose pH 6 containing a specific inhibitor As inhibitors we used 1×10^{-4} M eserine (eserine sulfate, Merck A. G., Darmstadt) or $3\times10^{-}$ M DFP (di-isopropylphosphorofluoridate B.D H Laboratory Chemicals Division, Poole) or $1\times10^{-3}-2\times10^{-4}$ M BW 284 C 51 ([1 5-bis (4-allyldimethylammoniumphenyl) pentan-3-one dibromide] Wellcome Research,

Chinchillas used in Italy were kindly supplied by Italian Society of Chinchilla, Florence. Chinchillas used in Germany were kindly supplied by Chinchilla-Zucht und Versuchsfarm J Wolf Onolzheim.

contd Table 4

Authors	Year	Method	Material	Results
Rossi et al	1964 *b*	Koelle Friedenwald	rabbit	After local injection of DFP N R in injected cristae ampullares. P R after restoration in normal conditions
Gacek et al	1965	Gomori	cat	Efferent vestibular fibers were more numerous than previously thought *They branch as they course peripherally* in the individual vestibular nerve rami After vestibular nerve section N R in every branch of vestibular nerve
Nomura et al	1965	Gomori	guinea pig	P R at base of sensory epithelium on slopes of crista ampullaris rather than on crest P R in ampullar nerves in axons of fine caliber fibers scattered throughout nerve bundle P R. in neuroepithelium of maculae sacculi and utriculi. Less activity in striola located in middle part of macula sacculi P R. in fibers scattered throughout nerves to saccule and utricle
Ishii et al	1967 *b*	Gomori	squirrel monkey	High P R in vestibular efferent bundles N R in Scarpa's ganglion cells. P R in fine efferent fibers distributed throughout peripheral vestibular organs.

Materials and Methods

Two adult guinea pigs and five adult chinchillas of both sexes were anesthetized with an endoperitoneal injection of sodium pentobarbital (35mg/kg). The inner ear was prefixed *in vivo* by a 10 min perilymphatic perfusion of the fixative at room temperature (IURATO and DE PETRIS, 1967). G Darmstadt) or 3×10 M DFP (di-isopropylphosphorofluoridate B D H Laboratory Chemicals Division, Poole) or 1×10^{-5} – $?\times10^{-4}$ M BW 284 C 51 ([1 5-bis (4-allyldimethylammoniumphenyl) pentan-3-one dibromide] Wellcome Research

Chinchillas used in Italy were kindly supplied by Italian Society of Chinchilla, Florence. Chinchillas used in Germany were kindly supplied by Chinchilla-Zucht and Versuchsfarm I. Wolf, Onolzheim.

Laboratories, Beckenham) or 1×10^{-5} – 2×10^{-4} M iso-OMPA (tetraisopropylpyrophosphorami de Koch Light Laboratories Ltd. Colnbrook). The incubation of this material was performed in a complete medium to which the inhibitors were added at the same concentration as used for the pre incubation. At these concentrations eserine completely inhibits AChE and ChE. DFP and iso-OMPA selectively inhibit the unspecific ChE. BW 284 inhibits AChE (BAYLISS and TODRICK 1956, PEARSE 1961, KOELLE and GROMADZKI 1966).

c) Pre incubation of the material in 1×10^{-4} eserine followed by incubation in a complete medium containing the inhibitor and having been prepared for at least 5 hr.

d) Incubation in a complete medium for 40 min of frozen and thawed specimens.

e) From other specimens 120 μ thick sections were obtained using a freezing microtome. The sections were put into KARNOVSKY's incubation medium for 10 min.

Following incubation the specimens were rinsed in 4 changes of cold 0.44 M sucrose for 10 min. They were then postfixed in a 1% osmium tetroxide buffered according to MILLONIG (1961) or with s-collidine (Eastman Organic Chemicals, Rochester, N.Y.). Dehydration was carried out in alcohol and embedding in Epon 812.

Thin sections cut with ultramicrotomes Sorvall MT I or LKB 4800 III were collected on Formvar-carbon membranes (DOWELL 1964, REALE and LUCIANO 1965) and stained by REYNOLDS (1963) or VENABLE and COGGESHALL's (1965) methods. The thin sections were examined in Siemens Elmiskop I and IA and Zeiss EM 9A electron microscopes. One μ thick sections obtained from the material embedded in Epon and mounted in glycerin were observed and photographed by phase contrast (Leitz Ortoplan).

Results

a) Preservation of the structure

The preservation of the organ of CORTI was constantly satisfactory after fixation both in glutaraldehyde and formaldehyde. The best results were obtained in material fixed in glutaraldehyde and incubated *in toto*.

On the contrary the vestibular sensory areas were not always well preserved. A remarkable shrinkage was often observed in the cytoplasm of the sensory cells whereas the nerve chalices were swollen. The best results were obtained in material fixed in formaldehyde and incubated *in toto*.

The preservation of the tissues was very poor in the frozen and thawed materials and in those sectioned using the freezing microtome. Breakdown of membranes, cytoplasmic retraction, vacuoles and mitochondrial alterations were frequently observed in all the tissues which were badly disrupted. Greater alterations were noted in the sensory cells type I and in the nerve chalices which were quite often expanded.

b) Histochemical localization of the reaction product in the organ of CORTI

Under the phase contrast microscope the organ of CORTI appeared to be the only portion

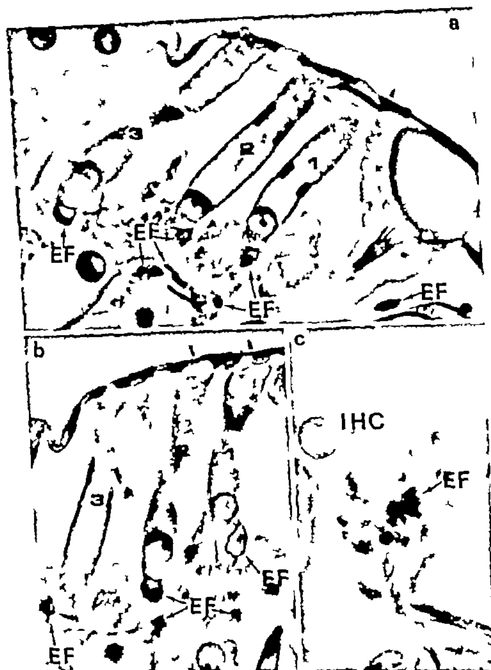

Fig. 1. Organ of Corti of chinchilla examined by phase contr 1 nd *b* the reaction product is localized below the outer hair cells (1, 2, 3) on the contour of the large efferent nerve endings (900 ×). *EF* = efferent fibers or endings. In dense reaction product can be seen below an inner hai cell (IHC). 1400 × Glutaraldehyde fixed material.

of the cochlear duct showing enzyme activity The reaction end product (Cu ferrocyanide) was clearly recognizable at the level of the inner spiral bundle below the inner hair cells (Fig. 1 c) the upper radial tunnel fibers (Fig 1 a) and some nerve endings below the outer hair cells (Fig. 1 a and b)

With the electron microscope the pictur was clearer and more precise The reactio product, which under the light microscope wa evident below the inner hair cells (Fig. 1 c) appeared localized in the inner spiral bundl (Fig. 2, 3 4 5) on the axolemma of the smal efferent fibers and of their presynaptic enlarge

F g The dense rea t m pr duct found nder the nner hair cell (IHC) is localized on the uter surf e f the small efferent f bers belonging t the nner pir l bundle (ISB) SC = pport g ell IP = m ner pillar ell E = endolymphatic pace 6,760 × Chinch lla glutaraldehyde fi ed material

Fig. 3. The small efferent fibers (EF) belonging to the inner spiral bundle and their enlargement (EL) show positive reaction on their plasma membrane. The large afferent radial fibers (AF) innervating an inner hair cell (IHC) appear negative except where they contact the efferent enlargements. The gap between the ending of one of these fibers and the plasma membrane of the inner hair cell is devoid of the reaction product (arrow). 24 000 ×. Chinchilla glutaraldehyde fixed material.

of the cochlear duct showing enzyme activity The reaction end product (Cu ferrocyanide) was clearly recognizable at the level of the inner spiral bundle below the inner hair cells (Fig 1 *c*) the upper radial tunnel fibers (Fig 1 *a*) and some nerve endings below the outer hair cells (Fig. 1 *a* and *b*)

With the electron microscope the picture was clearer and more precise The reaction product which under the light microscope was evident below the inner hair cells (Fig. 1 *c*), appeared localized in the inner spiral bundle (Fig. 2 3 4 5) on the axolemma of the small efferent fibers and of their presynaptic enlarge

Fig. 2 The dense react product fou d nder th nner hair cell (IHC) is localized on the ut r urf ce of the small efferent f bers belonging to the nner piral bundle (ISB). SC = supporting cell IP n ner pillar cell E = endolymph tic pace 6,760 × Ch n h lic glutar ldehyde f xed material

Fig. 4. The picture shows at higher magnification (60,000×) an afferent radial fiber (AF) in contact with several small efferent fibers (EF) and enlargement (EL). Shape and position of dark granules of the reaction product are visible. Subsequent sections of the contoured areas are shown in Fig. 5 and 6. Chinchilla, glutaraldehyde fixed material.

ments (Fig. 3 4) The reaction product was absent at the large afferent radial fibers (den drites of the cochlear ganglion cells) innerva ting the inner hair cells, except where they contact the efferent enlargements (Fig. 3 4 5) The endings of these afferent fibers were also devoid of the reaction product as well as the gap between them and the plasma membrane of the inner hair cells (Fig. 3)

The upper tunnel radial fibers (Fig. 6 *a* and *b*) and those of the spiral tunnel bundle showed a heavy precipitate on their outer surfaces. The reaction product was absent on the lower tunnel radial fibers (Fig. 6 *a*)

The large efferent nerve endings in contact with the base of the outer hair cells (axosomatic synapses) exhibited a large amount of the reaction product (Fig 7 8) This appeared deposited on the plasma membrane of the efferent endings and filled the synaptic gap between these endings and the plasma mem brane of the outer hair cells (Fig. 8 9 *a* 9 *b*) This gap which usually measures 215 225 A, (C A SMITH 1967 *a*) often appeared irregu larly enlarged the expanded zones always being filled with granules (Fig. 9 *b*) The subsynaptic cistern located inside the outer hair cells close to the efferent terminals, did not show the *reaction product (Fig. 9a 9 b) Granules were* present in the synaptic cleft of the axodendritic synapses described by C A SMITH and RASMUSSEN (1963) and by C A. SMITH (1967 *b*) below the outer hair cells (Fig 10 11) and on the plasma membrane of the efferent fibers located in the same region (Fig. 12)

It may be of some interest that, with the histochemical methods used in the present research the synaptic vesicles contained in the efferent nerve endings always appeared oblongated Instead after osmium tetroxide fixation or glutaraldehyde fixation not followed by incubation for AChE, the same vesicles appeared spherical

Most of the outer spiral fibers (dendrites of the cochlear ganglion cells) did not show the reaction product (Fig. 12) The afferent nerve endings in contact with the outer hair cells were also without reaction end product (Fig. 10) The gap between them and the plasma membrane of the outer hair cells did not generally contain the reaction product (Fig 10) Sometimes, only a few granules could be seen in this gap (Fig. 8). This happened when one or more efferents were in contact with the afferent nerve ending (Fig. 8) and never when several nerve endings all afferent, were in contact with each other (Fig. 10).

The non myelinated fibers in the spiral lamina showed a large amount of the reaction product on their outer surface Not having done specific research in this area we could not affirm if all these fibers were positive.

In all the above mentioned areas the reaction end product (Cu ferrocyanide) was granular and the size of the single granule was variable but generally rather large

A careful examination of the micrographs revealed an amorphous or very finely granulated precipitate coating the plasma membrane of the hairs and cuticle of the inner and outer hair cells (Fig. 13) and the free surface of the body of outer hair cells and pillars (Fig. 14). In these areas the amount of the precipitate was scarce if compared with that found on the plasma membrane of the efferent fibers and endings. The plasma membrane of the myelinated fibers in the osseous spiral lamina did not show a true precipitate but only an increased electron density (Fig. 15)

c) Histochemical localization of the reaction product in the vestibular sensory areas

In the vestibular labyrinth under the phase contrast microscope the reaction product (Cu-ferrocyanide) was only localized in the sensory areas Since the localization was similar in the cristae ampullares and in the maculae utriculi and sacculi to avoid repetition a unique description is given Inside the neuroepithelium

Fig 4 The picture show at higher magnification 60,000) an afferent radial fiber (AF) in contact with several small efferent fibers (EF) and enlargement (EL) Shape and position of dark granules of the reaction product are visible. Subsequent sections of the two contoured areas are shown in Fig 5 and 6 Chinchilla, glutaraldehyde fixed material.

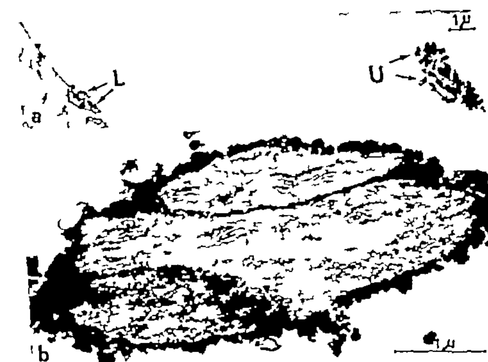
ments (Fig. 3 4) The reaction product was absent at the large afferent radial fibers (den drites of the cochlear ganglion cells) innerva ting the inner hair cells, except where they *contact the efferent enlargements* (Fig. 3 4 5) The endings of these afferent fibers were also devoid of the reaction product as well as the gap between them and the plasma membrane *of the inner hair cells* (Fig 3)

The upper tunnel radial fibers (Fig. 6 *a* and *b*) and those of the spiral tunnel bundle showed a heavy precipitate on their outer surfaces. The reaction product was absent on the lower tunnel radial fibers (Fig. 6 *a*)

The large efferent nerve endings in contact with the base of the outer hair cells (axosomatic synapses) exhibited a large amount of the reaction product (Fig. 7 8) This appeared deposited on the plasma membrane of the *efferent endings* and *filled the synaptic gap* between these endings and the plasma mem brane of the outer hair cells (Fig. 8 9 *a* 9 *b*) This gap which usually measures 215 225 A (C A SMITH 1967 *a*) often appeared irregu larly enlarged the expanded zones always being filled with granules (Fig 9 *b*) The subsynaptic cistern located inside the outer hair cells close to the efferent terminals did not show the reaction product (Fig 9*a* 9 *b*) Granules were present in the synaptic cleft of the axodendritic synapses *described by* C A SMITH *and* RASMUSSEN (1963) and by C A SMITH (1967 *b*) below the outer hair cells (Fig 10 11) and on the plasma membrane of the efferent fibers located in the same region (Fig 12)

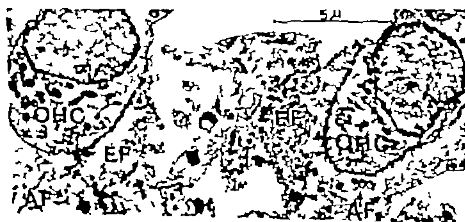
It may be of some interest that with the histochemical methods used in the present research the synaptic vesicles contained in the efferent nerve *endings always appeared* oblongated Instead after osmium tetroxide fixation or glutaraldehyde fixation not followed by incubation for AChE. *the same vesicles* appeared spherical

Most of the outer spiral fibers (dendrites of the cochlear ganglion cells) did not show the reaction product (Fig. 12) The afferent *nerve endings in contact* with the outer hair cells were also without reaction end product (Fig 10) The gap between them and the plasma membrane of the outer hair cells did not generally contain the reaction product (Fig 10). Sometimes only a few granules could be seen in this gap (Fig. 8) This happened when one or more efferents were in contact *with the afferent nerve ending* (Fig. 8) and never when several nerve endings, all afferent, were in contact with each other (Fig. 10).



The non myelinated fibers in the spiral lamina showed a large amount of the reaction *product on their outer surface. Not having* done specific research in this area we could not affirm if all these fibers were positive.

In all the above mentioned areas the reaction end product (Cu ferrocyanide) was granular *and the size of the single granule* was variable but generally rather large



A careful examination of the micrographs revealed an amorphous or very finely granulated precipitate coating the plasma membrane *of the hairs and cuticle of the inner and outer* hair cells (Fig. 13) and the free surface of the body of outer hair cells and pillars (Fig. 14). *In these areas* the amount of the precipitate was scarce if compared with that found on the plasma membrane of the efferent fibers and endings. The plasma membrane of the myelinated fibers in the osseous spiral lamina did not show a true precipitate but only an increased electron density (Fig. 15)

c) *Histochemical localization of the reaction product in the vestibular sensory areas*

In the vestibular labyrinth under the phase contrast microscope the reaction product (Cu-ferrocyanide) was only localized in the sensory areas. Since the localization was similar in the cristae ampullares and in the maculae utriculi and sacculi to avoid repetition a unique description is given Inside the neuroepithelium

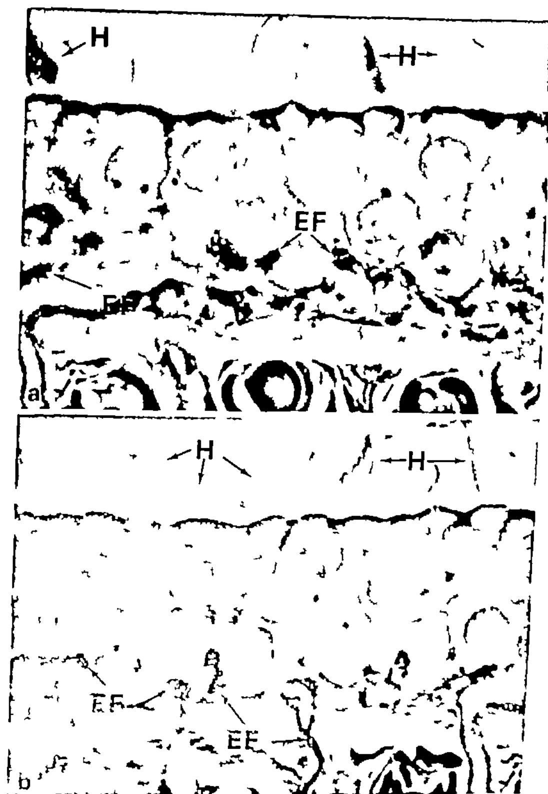
The controls with inhibitors (control *b*) indicated that the enzymatic activity was due to AChE.

(β) Controls *a* and *b* showed that the plasma membranes of hair cells and pillars and of myelinated fibers were more electron dense than other membranes fine granules were occasionally observed in some areas. It was concluded that this reaction depended on an artefact which at present is unidentifiable.



Freezing and thawing (controls *d* and *e*) caused remarkable morphological alterations. However the localization of enzymatic activity did not appear changed neither could different localizations be identified from those previously described

Discussion and interpretation of the results

The results of the present study generally agree with those obtained by SCHUKNECHT et al. (1959), VINNIKOV and TITOVA (1961 1962, 1963 1964) and DOHLMAN et al. (1958) with the light microscope in the cat, guinea pig and pigeon and by KANEKO (1968) and KANEKO and DALY (1968) with the electron microscope in the guinea pig.

The satisfactory preservation of the tissue and the relative fine distribution of the reaction product give course for discussion on the problems of (1) AChE localization and (2) possible significance of AChE activity in the inner ear

1. AChE localization

The localization of AChE activity at the electron microscope can be influenced by (a) fixation, (b) displacement of intermediate products and/or of the end product of the histochemical reaction and ( ) the steps following the histochemical reaction (e.g. rinsing, post fixation, dehydration and embedding) All these factors can give an incorrect interpretation of the results From this point of view the technique of KARNOVSKY and ROOTS (1964) has been thoroughly examined by the authors (KARNOVSKY 1964) and also by BLOOM and BARRNETT (1966). NOVIKOFF et al (1966) ERÄNKÖ et al (1967), ROBINSON and BELL (1967), ROBINSON (1969). Other histochemical methods that allow the localization of the same enzyme have been even more critically controlled (e.g. BROWN, 1961 BARRNETT 1962 BRZIN et al 1966 DAVIS and KOELLE, 1967). We have considered the results of these last studies because most of the techniques, includ ing those used by KARNOVSKY and ROOTS (1964) derive from the KOELLE and FRIEDENWALD's (1949) method

a) Fixation

It is well known that ChE are at least in part, firmly bounded to the cell structures (COUTEAUX, 1958 BARRNETT 1962 KARNOVSKY 1964 and others) and therefore not easily dif fusible However a fixation is advised for the following reasons to (α) assure the mor phological preservation of structures (ERÄNKÖ et al. 1967) (β) reduce enzymatic activity in the areas in which it is present in an excessive amount and obtain a clearer localization of the end product of the reaction (COUTEAUX, 1958), (γ) make the penetration of the com ponents of the incubation medium easier (BRZIN et al. 1966)

In the course of this study we used two fixatives, formaldehyde and glutaraldehyde. Formaldehyde inhibits ChE activity in different amounts according to the organ and type of animal (TAXI 1957). Inhibition has also been seen with glutaraldehyde (SABATINI et al 1963 BLOOM and BARRNETT 1966 NOVIKOFF et al 1966 and others). In our material formal dehyde gave a less evident (by judging the intensity of the reaction) inhibition of AChE activity The results were the same as those obtained by other authors on the same (KANEKO and DALY 1968) and on different materials

F g 26 Bel w the basement membrane of the utricle the react on product is localized on the non-myel nated nerve f bers (NM) MY = myelinated nerve fibers SC = Schwann cell 60,000 × Chinch lla F rmaldehyde f ed material

Discussion and interpretation of the results

The results of the present study generally agree with those obtained by SCHUKNECHT et al. (1959) VINNIKOV and TITOVA (1961 1962, 1963 1964) and DOHLMAN et al. (1958) with the light microscope in the cat, guinea pig and pigeon and by KANEKO (1968) and KANEKO and DALY (1968) with the electron microscope in the guinea pig.

The satisfactory preservation of the tissue and the relative fine distribution of the reaction product give course for discussion on the problems of (1) AChE localization and (2) possible significance of AChE activity in the inner ear

1. AChE localization

The localization of AChE activity at the electron microscope can be influenced by (*a*) fixation, (*b*) displacement of intermediate products and/or of the end product of the histochemical reaction and ( ) the steps following the histochemical reaction (e.g. rinsing, post fixation, dehydration and embedding). All these factors can give an incorrect interpretation of the results From this point of view the technique of KARNOVSKY and ROOTS (1964) has been thoroughly examined by the authors (KARNOVSKY 1964) and also by BLOOM and BARRNETT (1966) NOVIKOFF et al (1966), ERÄNKÖ et al ((1967), ROBINSON and BELL (1967), ROBINSON (1969) Other histochemical methods that allow the localization of the same enzyme have been even more critically controlled (e.g. BROWN, 1961 BARRNETT 1962, BRZIN et al 1966 DAVIS and KOELLE, 1967). We have considered the results of these last studies because most of the techniques, including those used by KARNOVSKY and ROOTS (1964) derive from the KOELLE and FRIEDENWALD's (1949) method.

a) Fixation

It is well known that ChE are, at least in part, *firmly* bounded to the cell structures (COUTEAUX 1958 BARRNETT 1962, KARNOVSKY 1964 and others) and therefore not easily diffusible However a fixation is advised for the following reasons to (α) assure the morphological preservation of structures (ERÄNKÖ et al 1967)· (β) reduce enzymatic activity in the areas in which it is present in an excessive amount and obtain a clearer localization of the end product of the reaction (COUTEAUX, 1958)· (γ) make the penetration of the components of the incubation medium easier (BRZIN et al. 1966).

In the course of this study we used two fixatives, formaldehyde and glutaraldehyde. Formaldehyde *inhibits* ChE activity in different amounts according to the organ and type of animal (TAXI, 1952). Inhibition has also been seen *with* glutaraldehyde (SABATINI et al 1963 BLOOM and BARRNETT 1966 NOVIKOFF et al. 1966 and others) In our material formaldehyde gave a less evident (by judging the intensity of the reaction) inhibition of AChE activity The results were the same as those obtained by other authors on the same (KANEKO and DALY 1968) and on different materials

(e.g. SHIMIZU and ISHII 1966; TERÄVÄINEN 1969 b). However BLOOM and BARRNETT (1966) noted that formaldehyde inhibits more or less the same as glutaraldehyde. The different results can be explained by various sources of aldehydes with different concentrations of the fixative and also with different fixation times.

We fixed the material *in vivo* using the perilymphatic perfusion method advised in the studies of the inner ear to obtain better morphological results (IURATO and DE PETRIS 1967). In other material fixation *in vivo* was advised to reduce or abolish a possible displacement of the enzyme (ROBINSON and BELL, 1967; ROBINSON 1969).

b) Diffusion of the intermediate products and/or of the end product of the reaction

KARNOVSKY's technique was chosen by us because it is simpler and adapted to the study of the inner ear. Moreover it does not give artefacts caused by « metallophilia », i.e. a bound between some tissue components (probably acid mucopolysaccharides) and metal ions (ZENKER 1969; LANGLEY 1969).

The end product of the reaction is insoluble in water and in the reagents used for embedding (KARNOVSKY 1964). NOVIKOFF et al. (1966) however did not exclude the possibility of its own displacement, although this only happens in unfixed materials. ROBINSON (1969) and TERÄVÄINEN (1969 a) thought that thiocholine released by enzymatic activity was diffusible. This diffusion should happen if the speed of substrate hydrolysis is greater than the speed of capture, that is to say in the places where the enzymatic activity is higher. In such a case one could have a "false negative reaction" (in the place of the true enzymatic activity) and a "false positive reaction" (where the thiocholine is diffused). In order to reduce or eliminate the diffusion it was suggested to partially inhibit enzymatic activity by a more or less prolonged fixation (BARRNETT 1962; ERÄNKÖ et al. 1967; SHIMIZU and ISHII 1966), by unfavourable pH (KARNOVSKY and ROOTS 1964), by lowering of temperature, duration of incubation (KARNOVSKY 1964), or by adding an inhibitor in weak concentration to the incubation medium (BARRNETT 1962). These devices give the best conditions to the histochemical localization of the enzymatic activity. Not knowing the place in the inner ear in which ChE activity is located in ... and above all how much could be found, the time of fixation was maintained constant and we varied the duration of the incubation which was carried out on ice. In this way diffusion was easily limited and identified.

c) Steps following the histochemical reaction

According to KARNOVSKY and ROOTS (1964) and KARNOVSKY (1964) these steps do not produce artefacts. KARNOVSKY (1964) said that counterstaining with an alcaline Pb solution does not influence the end product of the reaction. On the contrary we observed that the staining of the thin sections using a Pb citrate solution according to REYNOLDS (1963) can remove the end product of the reaction after 5 min. This artefact is very coarse and easily identifiable. It can be avoided if a quick staining method is used like that proposed by VENABLE and COGGESHALL (1955) which has lately been used by us.

On the basis of the criteria discussed in (a), (b) and (c) the results of the histochemical reaction obtained in the different areas of the membranous labyrinth can be critically examined and interpreted.

In the inner spiral bundle, where large Cu ferrocyanid crystals were observed, some axons were completely surrounded by the reaction product, some only partially and others not at all (Fig. 4). It could be thought that for the latter the reaction was negative. However serial sections demonstrated that the reaction was present where before it was

absent and vice versa (Fig. 5 *a, b*). The negative reaction of some axons probably depends on the large volume of crystals formed during incubation. The observation of serial sections therefore permits us to exclude a "false negative reaction".

Sometimes the gap between the small afferent nerve endings and the outer hair cells showed the end product of the reaction (Fig. 8). This could be interpreted as the result of a diffusion phenomenon (which produces a "false positive reaction") for the following reasons. (α) The reaction product was always located in larger quantities in the part of the gap closer to an efferent synapse. (β) In the middle and upper turns of the cochlea where the large efferent endings are less numerous, the small afferent nerve endings were usually completely negative (Fig. 10). (γ) The large efferent nerve endings showed an intense deposition of Cu-ferrocyanide not only in the synaptic gap but also on the whole plasma membrane besides the synaptic region. Instead, in the small afferent nerve endings the reaction product, when present, was only deposited in the part of the synaptic gap close to an efferent synapse. The present interpretation agrees with that of KANEKO and DALY (1968). The precipitate that was sometimes observed in the gap between the hair cell type II and the afferent endings (Fig. 20) could be interpreted in the same way.

The problem whether these "false localizations" depended on the diffusion of the reaction product or of the enzyme cannot be solved at present because the reaction product obtained by us is still too coarse. The problem could be resolved after having determined if the reaction product is caused by an enzymatic activity really present in the synaptic gap on both pre- and post-synaptic membranes or only on the pre- or on the post-synaptic membrane. The research carried out by DE LORENZO et al. (1969) and by TERAVAINEN (1967, 1969 *a, b*) demonstrated that a precise localization depends on many factors, which are particulary difficult to control in the inner ear.

The enlargements of the synaptic gap which were found in the efferent synapses, particularly at the level of the active zones, were probably due to the large size of the reaction product (Fig. 9–11). This interpretation rests on the following facts. (α) The synaptic gap is constant in width in the specimens not treated with histochemical methods. (β) In this area the enzymatic activity was high and the reaction product was formed in a large amount after only 30 min of incubation on ice in spite of glutaraldehyde fixation. (γ) The enlarged tracts of the synaptic gap always appeared completely filled by the reaction product.

The junction between the hair cells type I and the nerve chalices was always free of the reaction product (Fig. 18, 19, 24 *b*, 25). At this level a finely granular intercellular material is interposed in a regular manner between the plasma membrane of the hair cell and the nerve chalice (C. A. SMITH, 1967 c; HAMILTON, 1968). In order to be certain that the absence of AChE activity was not due to an inadequate penetration of the medium in this gap, particulary when the material was incubated *in toto*, we made some trials on frozen and thawed material and on sections cut using the freezing microtome. By these techniques severe morphological alterations were found in the neuroepithelium. However, this procedure did not produce a different localization of the enzymatic activity. We were therefore confident that the lack of enzymatic activity at the hair cell-chalice junction did not depend on an inadequate penetration of the medium.

As previously mentioned in the introduction, AChE activity was also observed in the cytoplasm of the hair cells with the aid of the light microscope (DEL BO and CONTI, 1961; VINNIKOV and TITOVA, 1961, 1962, 1963, 1964). However, in the present investigation although a careful examination of the electron micrographs, the reaction product was never found inside the hair cells nor in the nerve endings. It is a well known fact that with the aid of the electron microscope AChE activity

was observed in many cytoplasmic organelles of other tissues e g the synaptic vesicles, the endoplasmic reticulum and *sometimes the* Golgi apparatus (BARRNETT 1962 MILEDI *1964* BLOOM and BARRNETT *1966*) the neurotubules (SHIMIZU and ISHII 1966 DE LORENZO et al 1969) and the subsynaptic cistern (BRZIN et al. *1966*)

The discrepancy could depend on the difficulty of the components of the incubation medium to penetrate into the tissues (BELL, *1966* ERÄNKÖ *et al 1967* DAVIS *and* KOELLE 1967), when incubated *in toto* In this connection it may be recalled that many authors (e g COUTEAUX, 1958 KOELLE and FOROGLOU KERAMEOS 1965 KOELLE and GROMADZKI *1966) suggested a* pre incubation in a medium without substrate to obtain the penetration and the equilibrium of all the reagents inside the specimen before the substrate arrives at the active points. NOMURA (1966) on the other *hand* demonstrated in the inner ear with the light microscope a different localization of DPNH-diaphorase activity depending on the degree of the *penetration of the* incubation medium The penetration can be made easier by freezing and thawing the specimen resulting in the breaking of the plasma membranes BELL (1966) obtained a similar result with the light *microscope in the* central nervous system using KARNOVSKY and ROOTS technique for ChE

In order to be certain that the absence of AChE activity within the hair cells and in the nerve endings was not due to an inadequate *penetration of the medium we made some* trials on frozen and thawed material (control *f*) By freezing and thawing, severe morphological alterations were found in the organ of CORTI and in the vestibular sensory areas at *the electron microscopical* level However this procedure did not produce a different localization of the *enzymatic* activity It is evident that fixation was sufficient to diminish the barrier to diffusion of the incubation medium (BRZIN et al. 1966) which in our material consisted of only a few rows of cells.

The weak reaction we noted on the free surface of the hair cells could depend on (α) the inhibition *of the enzymatic activity by the* fixative or (β) an unspecific staining It must *be recalled that the* precipitate was only observed after fixation in formaldehyde and not in glutaraldehyde Since formaldehyde inhibits *less than glutaraldehyde ChE activity* one could conclude that the precipitate was due to a specific enzymatic reaction. Instead the controls indicated that the reaction was unspecific. Infact the precipitate was observed in *the material incubated* without substrate and in the presence of inhibitors. KANEKO and DALY (1968) noted a lesser quantity of precipitate on the cuticle and hairs of outer hair cells in material incubated without substrate and concluded *that* the reaction was due to AChE activity On the other hand the results obtained by us demonstrated that the precipitate was unspecific (Fig. 13 and 14) and was not due to enzymatic activity The reason for *this artefact has not yet been identified.*

A positive reaction was observed *on the* plasma membrane of myelinated nerve fibers by LEWIS and SHUTE (1966) NOVIKOFF et al. (1966) SCHLAEPFER and TORACK (1966) BRZIN et al. (1966) BRZIN and DETTBARN (1967). *SCHLAEPFER (1968) CSILLIK et al* (1968), DI LORENZO et al (1969) and other authors. UCHIZONO et al (1967) observed the same on the cochlear myelinated fibers. In our material the incubation medium penetrated with difficulty *into the* cochlear nerve fibers because the structure of the myelin sheath was well preserved This could explain *the weak reaction* we noted However ELFVIN (1961) and other authors (e g MALHOTRA and VAN HARREVELD, 1965) observed that the axolemma was thicker than the plasma membrane of Schwann cells *In our material* the densitometric trace (Fig 15) confirmed these observations and also showed that *the plasma membrane of myelinated* nerve

fibers was thicker than the plasma membrane of Schwann cells and major dense layers of myelin sheath. Since the densitometric trace of controls was similar, we concluded that the increased density was not due to the histochemical reaction.

Finally, after fixation in glutaraldehyde electron dense granules of 500 Å could be observed spread at random on all the cell structures. They were not present in the material incubated without substrate (control *a*); they were very numerous when the material was incubated in a stale medium (control *c*). In agreement with ROBINSON (1969) we think that these granules are unspecific and produced in the incubation medium by spontaneous hydrolysis of the substrate. ROBINSON avoided this inconvenience by a short incubation in a fresh medium, while our experiments using the same method were unsuccessful.

Summarizing, in the organ of CORTI and in the vestibular sensory areas AChE activity seems to be an exclusive property of efferent fibers, efferent nerve endings and synaptic enlargements along efferent presynaptic fibers.

2. Possible significance

The problem of the identification of the neurohumoral transmitter in the efferent olivocochlear bundle (OCB) is still open to discussion. On the basis of its AChE activity KOELLE (1955), CHURCHILL et al. (1956), SCHUKNECHT et al. (1959), ROSSI and CORTESINA (196) and SHUTE and LEWIS (1963) considered the efferent OCB as cholinergic. However, according to some more recent investigations the histochemical localization of AChE in an axon does not automatically identify that axon as cholinergic in the accepted sense (discussion in ROBINSON and BELL, 1967). As pointed out by ECCLES (1964), besides the histochemical one several other criteria have to be satisfied before one can have full confidence in identifying a substance as the synaptic transmitter of a system of nerve fibers. Particularly important are the neuropharmacological tests. Unfortunately in the case of the organ of CORTI the pharmacological tests have given contradictory results.

GISSELSSON (1950, 1960) applied acetylcholine (ACh) electrophoretically to the vicinity of the hair cells and found an increase of the cochlear microphonics (CM) amplitude. After intra-arterial injection of ACh, the action potentials (AP) of the auditory nerve rapidly disappeared but it was uncertain whether this was due to a specific effect or to a generalized action on the animal. A similar effect, namely inhibition of AP and augmentation of CM was obtained by FEX (1959, 1962) and by DESMEDT and MONACO (1960, 1961) with the electrical stimulation of the crossed efferent fibers. Thus GISSELSSON (1960) suggested that ACh was the transmitter substance of the crossed OCB fibers.

On the contrary KATSUKI et al. (1965), TANAKA and KATSUKI (1966) obtained opposite results, namely decrease of CM response and no effect on AP by applying ACh iontophoretically in the vicinity of the cochlear hair cells. Moreover, the local application of *d*-tubocurarine (DTC) in the vicinity of the hair cells does not influence the inhibition of AP caused by electrical stimulation of the OCB at the floor of fourth ventricle. These results suggest that the efferent fibers to the cochlea are noncholinergic.

Unfortunately neither GISSELSSON nor KATSUKI mentioned the concentrations of ACh they used. FEX (1968) estimated that the amount of ACh applied by GISSELSSON could be lower by a factor of 1,000 or more than the amount that KATSUKI et al. applied. Also the description of the DTC experiments made by TANAKA and KATSUKI is not sufficiently detailed. FEX (1968) applied DTC to the organ of CORTI of the cat using artificial perilymph to which 0.7×10^{-4} gr/ml of DTC chloride had

was observed in many cytoplasmic organelles of other tissues e g. the synaptic vesicles the endoplasmic reticulum and sometimes the Golgi apparatus (BARRNETT 1962 MILEDI 1964 BLOOM and BARRNETT 1966) the neurotubules (SHIMIZU and ISHII 1966 DE LORENZO et al 1969) and the subsynaptic cistern (BRZIN et al. 1966)

The discrepancy could depend on the difficulty of the components of the incubation medium to penetrate into the tissues (BELL, 1966 ERÄNKÖ et al 1967 DAVIS and KOELLE 1967) when incubated *in toto* In this connection it may be recalled that many authors (e g. COUTEAUX, 1958 KOELLE and FOROGLOU KERAMEOS 1965 KOELLE and GROMADZKI 1966) suggested a pre incubation in a medium without substrate to obtain the penetration and the equilibrium of all the reagents inside the specimen before the substrate arrives at the active points NOMURA (1966) on the other hand demonstrated in the inner ear with the light microscope a different localization of DPNH-diaphorase activity depending on the degree of the penetration of the incubation medium The penetration can be made easier by freezing and thawing the specimen resulting in the breaking of the plasma membranes BELL (1966) obtained a similar result with the light microscope in the central nervous system using KARNOVSKY and ROOTS technique for ChE

In order to be certain that the absence of AChE activity within the hair cells and in the nerve endings was not due to an inadequate penetration of the medium we made some trials on frozen and thawed material (control *d*) By freezing and thawing severe morphological alterations were found in the organ of CORTI and in the vestibular sensory areas at the electron microscopical level However this procedure did not produce a different localization of the enzymatic activity It is evident that fixation was sufficient to diminish the barrier to diffusion of the incubation medium (BRZIN et al 1966) which in our material consisted of only a few rows of cells.

The weak reaction we noted on the free surface of the hair cells could depend on (α) the inhibition of the enzymatic activity by the fixative or (β) an unspecific staining. It must be recalled that the precipitate was only observed after fixation in formaldehyde and not in glutaraldehyde Since formaldehyde inhibits less than glutaraldehyde ChE activity one could conclude that the precipitate was due to a specific enzymatic reaction Instead the controls indicated that the reaction was unspecific Infact the precipitate was observed in the material incubated without substrate and in the presence of inhibitors. KANEKO and DALY (1968) noted a lesser quantity of precipitate on the cuticle and hairs of outer hair cells in material incubated without substrate and concluded that the reaction was due to AChE activity On the other hand the results obtained by us demonstrated that the precipitate was unspecific (Fig. 13 and 14) and was not due to enzymatic activity The reason for this artefact has not yet been identified

Acknowledgements

My chief and teacher in oto-laryngology Professor Otto H. Meurman M.D Head of the Otolaryngological University Clinic, Turku, suggested this subject to me. During the course of this study he has given me good advice and thus greatly helped me to accomplish the study I wish to express my deep graditude to him.

X-ray crystallographic study in my investigation was carried out at the Institute of Physics, Turku University Head of this institute Professor Martti Kantola, Ph D kindly offered his apparatus to my disposal and showed unfailing interest for my work. In addition, I am thankful for his sound criticism.

I also wish to thank Professor Arje *Scheinin D.Odont Head of the Institute of* Dentistry Turku University for his permission to carry out the microradiographic part of my investigation at his institute.

I also thank Professor Lauri Saxén, M.D Head of the III Department of Pathology University of Helsinki, for his valuable criticism of the manuscript.

For good cooperation I am indebted to Mr Erkki Häsänen Lic.Technol. His help made it possible to carry out the mineral analyses of bone at the Reactor Laboratory of the Department of Technical Physics Technical University Otaniemi.

I am grateful to Mr Heikki Kahkönen, Ph.D who gave me good advice as to the crystallographic examination Miss Raija Puhakka, Mag.Phil. and Mr Jorma Puhakka, Mag.Pol. for their help in the statistical analysis of the results. I also wish to thank Mrs. Aili Ryynänen Mag.Phil. and her assistants for their help in collecting the literature Mrs. Liisa Karkola, Mag.Phil. for *translating this thesis into English*, and Mrs. Raija Koskinen for typing the manuscript.

Last but not least, I wish to thank my wife for her untiring patience and support during the course of the investigation.

H J Puhakka

I Introduction

Although probably *the first reports of otosclerotic* changes were published as early as in 1735 by Valsalva, it took almost 200 years before the histopathologic phenomena of this disease were understood more carefully. It is true that Politzer in 1894 described the otosclerotic process more in details, but only the twentieth century brought more defined information on the development of this disease. Yet the final answer to the question of the initiating factor of the process, which in its time leads to formation of abnormal ossification foci is still missing.

It has been discussed for a long time whether otosclerosis is a primary disease of the bony labyrinthine capsule or a local manifestation of a more generalized disease. The van der Hoeve syndrome has often been an object *of investigation in this connection.* In the same way the investigators have tried to found a connection between otosclerosis and osteogenesis imperfecta. Morrison & Bundley (1970) write however that there is no evidence to relate the two diseases in the language of clinical genetics. Bentzen (1966) on his behalf noted not infrequently different ectodermal and mesodermal abnormalities in his otosclerotic patients. This can be considered to mean a more generalized process.

Some experimental studies of otosclerosis have enriched the discussion on possible etiologic factors. Angeluscheff (1953) reports changes in the bone after ultrasonic exposure. He found similarities with the otosclerotic process and refers to prevalence of ultrasounds in our daily environment. Kristensen & Jorgensen (1967) examined the temporal bones of 165 patients and noted a relationship between irradiation and otosclerotic changes. Mendoza et al. (1969) irradiated labyrinthine capsules of dogs by x-rays and found foci resembling of otosclerosis. It is questionable whether these changes observed have any *connection with* the proper otosclerotic process.

According to Altmann (1962) the etiologic factors of otosclerosis can be constitutional, local or activating, and it is most likely that several factors exist that cause the pathologic process. According to Frost (1962) the primary etiologic factor is some change in the cement substance of the bony labyrinthine capsule. When we remember on the other hand that the organic component of the bone play a decisive role in initiating and developing the mineralizing process a change in the bone cement substance may *cause different disorders in the inorganic* component of the otosclerotic bone. Röckert et al. (1965) write: "One of the regions where basic information is lacking is the mineralizing process in otosclerosis. Among the numerous investigations on otosclerosis, there are only few which deal with the inorganic side of the process. This may be due to the small number of available methods. X-ray diffraction methods, electron microscopy, soft roentgen contact microradiography and, in recent years some other methods as well have given a chance to deepen our knowledge of the inorganic component of the bone. It is probable *that elucidation* of the inorganic component of the otosclerotic process does not give the final answer to the question of the initiating factor of otosclerosis, but the investigation may *give a hint at the direction* where the real cause should be sought.

II Review of the literature

A. Some aspects of ossification and bone crystals

Bone formation begins with the mesenchymal cells gradually changing into osteoblasts which are in their turn able to produce tropocollagen molecules and cement substance (Ham 1965) Although the fibroblasts in several tissues are able to form collagen osteoblasts only are able to produce cement substance typical of bone Tropocollagen molecules are of ultramicroscopic dimension and they have a constant chemical composition and fixed molecular weight Fibrils of different lengths and thicknesses are formed of tropocollagen by polymerization (Frost 1962)

Osteoblasts which form fibrous bone have chemical activity which differs in many respects from the activity of the osteoblasts which form lamellar bone Fibrous bone is formed very rapidly but it is structurally inferior Regular structure is lacking in it and its lacunae are not oriented. Normally fibrous bone is rapidly replaced by lamellar bone and human bones are almost exclusively lamellar Fibrous bone is most often imperfectly mineralized Frost (1962) has noted that otosclerotic bone very much resembles the fibrous bone that is seen in connection with osteomyelitis and healing fractures

The cause why the collagen of bone can alone start the mineralization process is still mostly unknown Neuman (1950) has suggested that there is an organic inhibitor which can be destroyed by alkaline phosphatase during calcification This inhibitor may be a polyphosphate and Fleisch & Neuman (1960) have observed its presence in serum ultrafiltrate and urine.

means that these fragments gradually grow into clearly defined crystals. In the nucleation phenomenon, the nuclei probably grow in the way that new molecules atoms and ions gradually come into the nucleus (Glimcher 1959) Recrystallization means the growth of large crystals at the expense of smaller ones.

The shape, size and orientation of bone crystals can be examined by virtue of x-ray diffraction. Due to the relatively small size of bone crystals the diffraction lines are, however broad and somewhat indistinct causing difficulties in estimating the results. For the same reason it is not easy to carry out a crystallographic examination between different suggested bone structures. The exact composition of the bone is still discussed. Yet, a generally accepted view is that the physical unit of bone is apatite, more closely hydroxyapatite crystal (Carlstrom & Glas 1959 Glimcher 1959 Engström 1960) The chemical structure of the unit cell represents the formula $Ca_{10}(PO_4)_6(OH)_2$ (Fig. 1)

Apparently collagen fibrils primarily determine the size and shape of bone crystals. Organic molecules influence the growth of inorganic crystals (Seifert 1953) Termine & Posner (1967) have shown that big part of bone minerals are in noncrystalline amorphous phase. It has been suggested that bone crystals are large hexagonal plates 500 x 250 x 100 $Å^2$ in size (Robinson 1952) but the most often accepted view is that bone crystals are needle-shaped particles with a thickness of 15 to 30 Å and length of 200 to 400 Å (Glimcher 1959 Frost 1962) Nevertheless a considerable variation in the length of the crystals is possible (Eanes & Posner 1970)

In his monograph, Aho (1966) has presented a general survey of appearance location in respect to collagen fibrils and variations in the shape of bone crystals. Robinson & Cameron (1956) have showed electron microscopically that the long axis

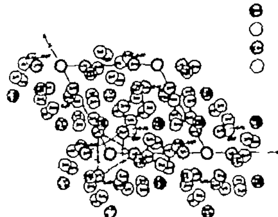

Fig. 1 The hydroxyapatite structure projected onto the a, b plane. The solid lines drawn between the hydroxyl positions outline the unit cell edges. The centers of the open circles mark the x, y positions of the atoms. The z parameters are the numbers written within the circles. (From Eanes & Posner 1970)

of bone crystals is parallel to the fibrils, but in the crystallizing cartilage crystals are not oriented. Similarly Clark & Iball (1957) have pointed out that crystals in embryonic bone are not oriented. Crystal orientation varies not only from bone to bone but also in different locations of the same bone. Collagen fibrils are hardly either oriented in embryonic bone (Glimcher 1959) The fact that the crystals are not oriented is not due to the crystals themselves, but the indefinite location of collagen fibrils. The most important reason for orientation of inorganic bone crystals is the asymmetric growth of small crystals within the collagen fibrils, between tightly packed, longitudinally oriented chains of macromolecules (protofibrils)

Bast & Anson (1949) rather carefully described the general structure of the auditory

II Review of the literature

A. Some aspects of ossification and bone crystals

Bone formation begins with the mesenchymal cells gradually changing into osteoblasts which are in their turn able to produce tropocollagen molecules and cement substance (Ham 1965) Although the fibroblasts in several tissues are able to form collagen osteoblasts only are able to produce cement substance typical of bone Tropocollagen molecules are of ultramicroscopic dimension and they have a constant chemical composition and fixed molecular weight Fibrils of different lengths and thicknesses are formed of tropocollagen by polymerization (Frost 1962)

Osteoblasts which form fibrous bone have chemical activity which differs in many respects from the activity of the osteoblasts which form lamellar bone Fibrous bone is formed very rapidly but it is structurally inferior Regular structure is lacking in it and its lacunae are not oriented. Normally fibrous bone is rapidly replaced by lamellar bone and human bones are almost exclusively lamellar Fibrous bone is most often imperfectly mineralized Frost (1962) has noted that otosclerotic bone very much resembles the fibrous bone that is seen in connection with osteomyelitis and healing fractures

The cause why the collagen of bone can alone start the mineralization process is still mostly unknown Neuman (1950) has suggested that there is an organic inhibitor which can be destroyed by alkaline phosphatase during calcification This inhibitor may be a polyphosphate and Fleisch & Neuman (1960) have observed its presence in serum ultrafiltrate and urine

Calcification theories can be divided into three classes (1) those which propose mechanisms that would raise locally the $(Ca)x(PO_4)$ solution product to levels at which apatite would precipitate spontaneously (2) those which propose mechanisms that would create nucleating sites, or remove barriers to these sites, at local calcifying areas and (3) those theories which propose that apatite does not precipitate directly from serum but that a less basic calcium phosphate salt is formed initially which then hydrolyzes into apatite (Eanes & Posner 1970)

Weidmann (1963) thinks that mineralization of bone is a complicated and multiphase event There are three different possibilities that can initiate mineralization (1) collagen has a special function in the initiation of calcification (2) a combination of chondroitin sulphate and collagen has significance in providing the initial stimulus for mineralization (3) phosporylated collagen or phosphorylated component in ground substance acts as the initiating factor

According to Taves (1965) the most popular hypothesis for the mechanisms of normal calcification — diffusion of all ions and nucleation by the matrix — has been shown to be insufficient More evidence is needed to establish the suggestion that collagen nucleate at all Considerations of some type of pump mechanism or booster is according to Taves potentially useful.

Crystallization which means formation of inorganic crystals in a place where they have not existed previously represents a phase change This physical change in state can be divided into crystal nucleation which means formation of the initial fragments of the new phase and crystal growth which

means that these fragments gradually grow into clearly defined crystals. In the nucleation phenomenon, the nuclei probably grow in the way that new molecules atoms and ions gradually come into the nucleus (Glimcher 1959) Recrystallization means the growth of large crystals at the expense of smaller ones.

The shape, size, and orientation of bone crystals can be examined by virtue of x-ray diffraction. Due to the relatively small size of bone crystals the diffraction lines are, however broad and somewhat indistinct causing difficulties in estimating the results. For the same reason it is not easy to carry out a crystallographic examination between different suggested bone structures. The exact composition of the bone is still discussed. Yet a generally accepted view is that the physical unit of bone is apatite more closely hydroxyapatite crystal (Carlström & Glas 1959 Glimcher 1959 Engström 1960) The chemical structure of the unit cell represents the formula $Ca_{10}(PO_4)_6(OH)_2$ (Fig. 1)

Apparently collagen fibrils primarily determine the size and shape of bone crystals. Organic molecules influence the growth of inorganic crystals (Seifert 1953) Termine & Posner (1967) have shown that a big part of bone minerals are in noncrystalline amorphous phase. It has been suggested that bone crystals are large hexagonal plates 500 x 250 x 100 Å³ in size (Robinson 195) but the most often accepted view is that bone crystals are needle-shaped particles with a thickness of 15 to 30 Å and length of 200 to 400 Å (Glimcher 1959 Frost 1962) Nevertheless a considerable variation in the length of the crystals is possible (Eanes & Posner 1970)

In his monograph, Aho (1966) has presented a general survey of appearance, location in respect to collagen fibrils and ariations in the shape of bone crystals. Robinson & Cameron (1956) have showed electron microscopically that the long axis of bone crystals is parallel to the fibrils but in the crystallizing cartilage crystals are not oriented. Similarly Clark & Iball (1957) have pointed out that crystals in embryonic bone are not oriented. Crystal orientation varies not only from bone to bone but also in different locations of the same bone. Collagen fibrils are hardly either oriented in embryonic bone (Glimcher 1959) The fact that the crystals are not oriented is not due to the crystals themselves but the indefinite location of collagen fibrils. The most important reason for orientation of inorganic bone crystals is the asymmetric growth of small crystals *within* the collagen fibrils, between tightly packed, longitudinally oriented chains of macromolecules (protofibrils)

Fig. 1 The hydroxyapatite structure projected onto the a, b plane. The solid lines drawn between the hydroxyl positions outline the unit cell edges. The centers of the open circles mark the x, y positions of the atoms. The z parameters are the numbers written within the circles. (From Eanes & Posner 1970.)

B. Arrangement of collagen fibrils and bone crystals in the auditory ossicles and otosclerotic focus

1 The auditory ossicles

Bast & Anson (1949) rather carefully described the general structure of the auditory

ossicles On the other hand the periodic structure and arrangement of collagen fibrils are not presented in their investiga tion. According to them the stapedial foot plate is only partly osseous and partly cartilaginous Wustrow (1956) made a series of section samples of the auditory ossicles He found that irregularly located fibrils are however arranged by a certain princi ple. Differences in histologic pictures are due to different cut surfaces of fibril ag- gregations Chevance (1961) examined the arrangement of collagen fibrils in the audi- tory ossicles of man calf and Guinea pig and observed that collagen fibrils in the malleus incus and the stapedial crura are arranged in bundles A more irregular ar rangement was found in the stapedial foot plate which in Chevance s opinion was due to the fact that the stapedial footplate originates from the labyrinthine capsule Reydon & Smith (1968) examined the foot plate of the normal stapes by light and electron microscope and noticed remarkable structural variability in the order of collagen fibrils A lamellar arrangement of some of the collagen fibrils resembling the haversian system was present

There are very few references to crystallo- graphy of the auditory ossicles in the literature Meurman et al. (1967 1968) examined the crystalline structure of normal auditory ossicles and otosclerotic foci by the Debye-Scherrer method They noted that x ray crystallographic characteristics of normal auditory ossicles closely corre sponded to those of normal human bone A conclusion could thus be drawn that the crystalline structure of normal auditory ossicles does not differ from that of normal human bone

2 *Otosclerotic focus*

Weber (1931) examined the arrangement of collagen fibrils in otosclerotic foci in polar ized light and found that the fibrils were broken abgeschnitten" in the edge of the focus. In addition there were concavities in the fibrils. According to Weber the fibrils in the focus clearly differ from those outside the focus.

In their investigation on otosclerotic foci at different stages Chevance et al. (1961a) found that at the destruction phase collagen fibrils were broken as if they were cut with a knife and that this collagenolysis is a purely biochemical phenomenon because no cellular reaction is observed. In the electron microscope Chevance (1962) was able to distinguish different collagen changes at a great magnification

Müller (1964) thinks that it is possible to conclude upon the maturity of a otosclerotic focus from the form and arrangement of bone fibrils In an inactive focus the ar rangement of the fibrils is parallel and circulatory In an active phase on the contrary the arrangement form and thick ness of the fibrils vary a great deal. In some cases no fibrils can be seen. In their electron microscopic investigations Reydon & Smith (1968) found that in the central parts of the marrow spaces no connective tissue fibers were present On the other hand a great number of osteoblasts and their cytoplasmic processes were seen but no osteoclasts at all In the inactive parts collagen fibrils were mainly irregularly ar ranged

The crystalline structure of otosclerotic bone has been examined very little Meur man et al (1967 1968) used x ray diffraction methods and examined 200 otosclerotic foci or otosclerotic footplates in all In most of the samples the crystalline structure of otosclerotic bone was identical with that of normal human bone In one part of the samples no clear crystalline structure was distinguished at all and in another minor part a structure different from the crystal- line structure of normal hydroxyapatite was noted The authors suggested that these pathologic crystalline structures might

represent a mature inactive otosclerotic focus.

Frank et al. (1968) elucidated crystallography of otosclerotic foci by using electron microscopy and electronic diffraction in their investigations. In their diffraction photographs a part of the apatite lines had disappeared, and in addition they were broad and indistinct. The authors concluded on the basis of this that the crystals were small. In the electron microscope they were able to see the reduced size of the crystals.

C. Histochemical structure of the otosclerotic focus

To-day a great deal is known about what happens in the otosclerotic focus but very little about the initiating factor of this process. When examining otosclerosis by electron microscopy Chevance et al. (1969) noted that there were microfoci between the focus and normal tissue demonstrable only in the electron microscope. The focus appears to enlarge by fusion of these microfoci. In Gussen's (1968) opinion formation and spreading of otosclerotic bone are two quite different processes. The former is new bone formation within fibrous tissue and the latter invasive bone spreading.

Keleman & Linthicum (1969) in their turn think that every otosclerotic focus contains a spongiotic and sclerotic portion, which can always be sharply divided from each other. They did not find any cases of so-called burned out foci in old patients or of preotosclerosis around the advancing focus.

Some investigators suggest that decalcification of bone in otosclerotic process proceeds without osteoclasts (Lempert & Wolff 1949, Wolff & Lempert 1965, Chevance et al. 1969) whereas others consider osteoclasts a very important factor in this process (Weber 1960). Insufficiency of osteoblasts has been taken for the primary factor of otosclerosis (Hall & Oglivie 1961, Hoogland 1962, Hall & Oglivie 1964). Since the foci usually spread along the vascular spaces (Hall 1952, Wolff & Lempert 1965) it has been suggested that vascular changes participate in the genesis of decalcification (Lempert & Wolff 1949). Mendoza & Rius (1966) found obliteration of a large number of arteries in otosclerotic bone and Riiedi (1969) noted abnormal vascular connections between the membranous labyrinth and focus. Chevance et al. (1969) observed by electron microscopy that the endothelial cells of capillary network of the focus appeared to be normal.

Chevance et al. (1961a) proposed that collagen fibrils and ground substance play a decisive role in the development of otosclerosis. Ardouin & Wegmann (1961) observed that mucopolysaccharides and polysaccharides are disturbed in the otosclerotic focus. Arslan & Ricci (1961) noted deep alterations in the osteomucoid substance too. Ricci (1962) found an abnormal accumulation of mucopolysaccharides in the otosclerotic focus. He suggested that the primary cause of otosclerosis is a change of ground substance. Privara (1966) stated that the reaction of acid mucopolysaccharide in the otosclerotic focus is positive during the stage of breakdown and transformation of bony tissue and negative during the inactive phase.

Wolff & Bellucci (1960) suggested that some enzyme is the initiating factor of decalcification. Later on, efforts has been made to find possible changes in enzyme activities in the otosclerotic focus. Chevance et al. (1961b) noted that there is alkaline phosphatase in the focus at the first phase and during the whole second phase, too until the bone is completely calcified. There after alkaline phosphatase disappears. The enzyme was always located extracellularly except in osteoblasts, where it was intracellular. Ricci (1962) observed as well that the activity of alkaline phosphatase increases in the focus. He found alkaline phosphatase both in osteocytes and ground substance.

ossicles On the other hand the periodic structure and arrangement of collagen fibrils are not presented in their investigation According to them the stapedial foot plate is only partly osseous and partly cartilaginous Wustrow (1956) made a series of section samples of the auditory ossicles He found that irregularly located fibrils are however arranged by a certain principle. Differences in histologic pictures are due to different cut surfaces of fibril aggregations Chevance (1961) examined the arrangement of collagen fibrils in the auditory ossicles of man calf and Guinea pig and observed that collagen fibrils in the malleus incus and the stapedial crura are arranged in bundles A more irregular arrangement was found in the stapedial foot plate which in Chevance s opinion was due to the fact that the stapedial footplate originates from the labyrinthine capsule. Reydon & Smith (1968) examined the foot plate of the normal stapes by light and electron microscope and noticed remarkable structural variability in the order of collagen fibrils A lamellar arrangement of some of the collagen fibrils resembling the haversian system was present

There are very few references to crystallography of the auditory ossicles in the literature. Meurman et al (1967 1968) examined the crystalline structure of normal auditory ossicles and otosclerotic foci by the Debye Scherrer method They noted that x ray crystallographic characteristics of normal auditory ossicles closely corresponded to those of normal human bone A conclusion could thus be drawn that the crystalline structure of normal auditory ossicles does not differ from that of normal human bone

2 *Otosclerotic focus*

Weber (1931) examined the arrangement of collagen fibrils in otosclerotic foci in polarized light and found that the fibrils were broken abgeschnitten in the edge of the focus. In addition there were concavities in the fibrils According to Weber the fibrils in the focus clearly differ from those outside the focus

In their investigation on otosclerotic foci at different stages Chevance et al (1961a) found that at the destruction phase collagen fibrils were broken as if they were cut with a knife and that this collagenolysis is a purely biochemical phenomenon because no cellular reaction is observed. In the electron microscope Chevance (1962) was able to distinguish different collagen changes at a great magnification.

Müller (1964) thinks that it is possible to conclude upon the maturity of a otosclerotic focus from the form and arrangement of bone fibrils In an inactive focus the arrangement of the fibrils is parallel and circulatory In an active phase, on the contrary the arrangement form, and thickness of the fibrils vary a great deal In some cases no fibrils can be seen. In their electron microscopic investigations Reydon & Smith (1968) found that in the central parts of the marrow spaces no connective tissue fibers were present. On the other hand a great number of osteoblasts and their cytoplasmic processes were seen but no osteoclasts at all In the inactive parts collagen fibrils were mainly irregularly arranged.

The crystalline structure of otosclerotic bone has been examined very little. Meurman et al (1967 1968) used x ray diffraction methods and examined 200 otosclerotic foci or otosclerotic footplates in all In most of the samples the crystalline structure of otosclerotic bone was identical with that of normal human bone In one part of the samples no clear crystalline structure was distinguished at all and in another minor part a structure different from the crystal line structure of normal hydroxyapatite was noted. The authors suggested that these pathologic crystalline structures might

patients and increase in others. Seifert (1937) observed hypercalcemia and hypophosphatemia and increased secretion of calcium in urine.

Fowler (1947) did not see any differences in the calcium and phosphorus contents in investigations with identical twins. In a more extensive investigation of his Fowler (1948a) noted that there was inorganic phosphorus less than 3,5 mg % in 62 % of the men and 66 % of the women. Values of phosphorus were less than 3,5 mg % in two thirds of those whose calcium content was under 9,5 mg % and values of calcium did not reach up to 9,5 mg % in two thirds of those whose phosphorus was less than 3,5 mg %. Fowler considered the changes in the calcium and phosphorus contents general in otosclerotic patients. The reason why these changes were not great was in his opinion the fact that the examinations had been carried out a remarkable time after the onset of the active period of the disease. He thougt that because the lesion of otosclerosis is limited to the petrous bone it cannot cause very great changes in the composition of serum. On the other hand, Riskaer (1949) did not find significant differences in the calcium and phosphorus contents of serum between otosclerotic and control patients. Maurer (1956, 1958) also discussed the significance of calcium and phosphorus values of serum in the genesis of otosclerosis. In a material of 73 otosclerotic patients Volokhonskaya & Gukovich (1966) noted that generally the sodium concentrations had increased and potassium concentrations had decreased.

Alkaline phosphatase is the most important enzyme associated with ossification. That is why investigators of otosclerosis have always been interested in it. Fowler (1948a) noted that the activity of alkaline phosphatase in serum was within the limits of normal in those otosclerotic patients whose calcium concentrations had not decreased. Riskaer (1949) could not find values different from the normal ones. On the other hand, Maurer (1958) noted that the activity of alkaline phosphatase had decreased. In their well-controlled investigations Soifer et al. (1965) did not observe significant differences in alkaline phosphatase activities in otosclerotic patients and healthy controls.

Activities of other enzymes in the serum of otosclerotic patients have also been examined in order to find a cause for the disease process. Jakabfi et al. (1951) measured cholinesterase activity but did not observe a significant difference compared with normal patients. Timen (1964) noted that the level of cholinesterase activity was elevated after operations for otosclerosis in patients who suffered from vestibular disorders. The corresponding change was not observed in pseudocholinesterase activity.

Otosclerosis often progresses during pregnancy and that is why different questions of hormone metabolism form an interesting group of problems. The connection e.g., between steroids and bone metabolism is a well-known fact. A correlation between otosclerosis and the sex glands was observed as early as in 1937 by Seifert. In addition, he noted that metabolites of parathyroid were increased in otosclerotic patients. Fowler (1948b) emphasized the role of estrogen in otosclerosis. Patroni (1952) again suggested hypofunction of hypophysis, hypogenitalism, hypothyrosis and hyperparathyrosis. Maggio & La Fianza (1952) found decreased secretion of 17-ketosteroids in urine in 47 % of their series. In 25 % the secretion was increased and in 28 % it was normal. Nylén & Nylén (1952) also emphasized the role of the endocrine system in the genesis of otosclerosis. Cassano (1953) stated that secretion of 17-ketosteroids in urine was increased and equally strong in men and women.

Hermann & Maurer (1955) observed, on the other hand, decreased secretion of neutral 17-ketosteroids in otosclerosis. Mau-

In recent years several investigations have also elucidated the appearance of many other enzymes in the otosclerotic focus. Albernaz & Covell (1961) noted that succinic dehydrogenase activity was intensely positive for blood vessels and connective tissue spaces of the otosclerotic focus. Ardouin & Wegmann (1961) observed that there are several disordered enzymes in the focus both with increased and decreased activities. Soifer et al (1969 a) observed decrease in lactate and malate dehydrogenase activities and increase in alkaline phosphatase activity in the otosclerotic stapes

Chevance et al (1963) found cells in the stapes and labyrinthine capsule which were assumed to be able to phosphorylize glucose and form glycogen. Identical cells are seen in the otosclerotic focus but not in healthy bone. Chevance (1964) found sulfhydryl groups in the focus. In his opinion this indicates proteolytic activity Velican & Cinda (1967) revealed in vitro a total disintegration of the matrix of the stapes resembling pathologic lysis of an osteosponginous focus subjected to the action of sialidase and collagenase.

D Microradiography and its application in investigations on otosclerosis

Soft roentgen contact microradiography has made determination of mineral salts in the bone possible (Cosslet et al. 1957 Glimcher 1959) Karlsson et al (1954) were the first investigators to examine the temporal bone by microradiographic methods They prepared 100 to 200 μm thick sections of the malleus and incus and the bony labyrinthine capsule and made microradiographs of the sections Orlandini & Vidoni (1955) examined the effect of chronic otitis media on the auditory ossicles by the same method. Orlandini & Sbernini (1956) employed the method for studying the auditory ossicles of persons at various ages. Frost (1958) developed a method by means of which undecalcified bone sections of the thickness of 3 to 100 μm were made by manual grinding Hallen & Röckert (1960) reported a method by which they made plane-parallel sections. The thickness of these sections could be determined with the accuracy of ± 2 μm Danic et al (1963) examined normal and ostitic auditory ossicles. Ericsson (1965) also developed a method for examining the mineral content of bone The principle of this method is that investigators are able to prepare accurate plane-parallel undecalcified bone sections of which microradiographs are made. The contrast differences of these microradiographs were measured by complicated arrangements in a photometer

Aliprandi (1963) examined otosclerotic foci by microradiographic methods after embedding samples of bone in methyl methacrylate Claree (1964) also determined the degree of mineralization in otosclerotic bone by preparing 40 μm thick undecalcified sections. He used however electron microscopy Garcia Ibañez (1968) examined 46 samples of otosclerotic bone by microradiography by using undecalcified 30 to 50 μm thick sections. He also made traditional histologic preparations of the same samples and divided the foci into four developmental stages. Thus the microradiographs could be grouped in four different stages as well Meurman et al (1968) employed microradiographic methods in examining mineral distribution of otosclerotic foci with different crystalline structures

E. Changes in serum composition associated with otosclerosis

When examining mineralization of the otosclerotic process many investigators have elucidated the possible changes that are reflected in the serum composition Breitmann (1933) noted decrease in the calcium content of serum in some otosclerotic

patients and increase in others. Seifert (1937) observed hypercalcemia and hypophosphatemia and increased secretion of calcium in urine.

Fowler (1947) did not see any differences in the calcium and phosphorus contents in investigations with identical twins. In a more extensive investigation of his, Fowler (1948a) noted that there was inorganic phosphorus less than 3,5 mg % in 62 % of the men and 66 % of the women. Values of phosphorus were less than 3,5 mg % in two thirds of those whose calcium content was under 9,5 mg % and values of calcium did not reach up to 9,5 mg % in two thirds of those whose phosphorus was less than 3,5 mg %. Fowler considered the changes in the calcium and phosphorus contents general in otosclerotic patients. The reason why these changes were not great was in his opinion the fact that the examinations had been carried out a remarkable time after the onset of the active period of the disease. He thougt that because the lesion of otosclerosis is limited to the petrous bone it cannot cause very great changes in the composition of serum. On the other hand Riskaer (1949) did not find significant differences in the calcium and phosphorus contents of serum between otosclerotic and control patients. Maurer (1956, 1958) also discussed the significance of calcium and phosphorus values of serum in the genesis of otosclerosis. In a material of 73 otosclerotic patients Volokhonskaya & Gukovich (1966) noted that generally the sodium concentrations had increased and potassium concentrations had decreased.

Alkaline phosphatase is the most important enzyme associated with ossification. That is why investigators of otosclerosis have always been interested in it. Fowler (1948a) noted that the activity of alkaline phosphatase in serum was within the limits of normal in those otosclerotic patients whose calcium concentrations had not decreased. Riskaer (1949) could not find values different from the normal ones. On the other hand, Maurer (1958) noted that the activity of alkaline phosphatase had decreased. In their well-controlled investigations Soifer et al. (1965) did not observe significant differences in alkaline phosphatase activities in otosclerotic patients and healthy controls.

Activities of other enzymes in the serum of otosclerotic patients have also been examined in order to find a cause for the disease process. Jakabfi et al. (1951) measured cholinesterase activity but did not observe a significant difference compared with normal patients. Timen (1964) noted that the level of cholinesterase activity was elevated after operations for otosclerosis in patients who suffered from vestibular disorders. The corresponding change was not observed in pseudocholinesterase activity.

Otosclerosis often progresses during pregnancy and that is why different questions of hormone metabolism form an interesting group of problems. The connection, e.g., between steroids and bone metabolism is a well-known fact. A correlation between otosclerosis and the sex glands was observed as early as in 1937 by Seifert. In addition, he noted that metabolites of parathyroid were increased in otosclerotic patients. Fowler (1948b) emphasized the role of estrogen in otosclerosis. Patroni (1952) again suggested hypofunction of hypophysis, hypogenitalism, hypothyrosis and hyperparathyrosis. Maggio & La Fianza (1952) found decreased secretion of 17-ketosteroids in urine in 47 % of their series. In 25 % the secretion was increased and in 28 % it was normal. Nylén & Nylén (1952) also emphasized the role of the endocrine system in the genesis of otosclerosis. Cassano (1953) stated that secretion of 17-ketosteroids in urine was increased and equally strong in men and women.

Hermann & Maurer (1955) observed, on the other hand, decreased secretion of neutral 17-ketosteroids in otosclerosis. Mau-

rer (1958) carried out investigations on hormones in patients suffering from otosclerosis and he considered his findings reduced production of androgen Vyslonzil (1961) found even five times as high estrogen levels as normally in male patients decrease of gonadotrophin being always present In as few as 20 per cent the estrogen values were normal and in these cases 17 ketosteroid levels were remarkably low Vyslonzil (1963) found additionally that in male patients the estrogen levels were two to fivefold by the 50th year of age. He thought that the increase was due to elevated activity of Leydig's cells In their series of 73 otosclerotic patients Volokhonskaya & Gukovich (1966) noted depressed level of free 17-oxycorticosteroid secretion both before and after administration of ACTH They regarged it as a disorder of the function of mineralocorticoids in the adrenal cortex. Tarasenkova (1967) noted a direct correlation between the development of clinical manifestations of otosclerosis and the periods of physiologic rise of the estrogen content in the organism

Attempts have been made to elucidate the role of different vitamins in the otosclerotic process by examining the effect of vitamins as a possible treatment and by determining vitamin concentrations in serum (Weber 1932 Koch 1949 Grimaldi 1956 Ferreri 1957) The results of these investigations seem however to be less significant

Riskaer (1949) examined the total protein globulin and albumin in the serum of otosclerotic patients but he did not find any values different from the normal ones Vyslonzil (1954) suggested the alfa and beta globulin levels in serum to be elevated and this he considered to be associated with the hormones of the adrenal

Hlaváček et al (1955) and Hlaváček & Opplt (1957) noted elevated alfa and beta globulin values in otosclerotic patients. Soifer et al (1963) did not find abnormal levels of haptoglobins in serum. In his series of 35 otosclerotic patients Naumann (1964) found decreased albumin values and minor increases in the beta and gamma globulins In their investigation on urinary excretion of amino acids and hexosamine Schoenheyder et al (1966) found no significant variation from control patients.

Senff (1947) found elevated protein levels in cerebrospinal fluid of some otosclerotic patients Schindler et al (1965) analysed the perilymph of 122 otosclerotic patients and noted that it is comparable particularly with capillary serum These investigations were continued by Schindler & Schneider (1966) Chládek & Opplt (1966) noticed a lowered content of alfa and beta globulin fractions in the perilymph of patients with severe otosclerosis Further Chládek & Opplt (1968) established that there was a relationship between the range of the protein spectrum in the perilymph and the activity of otosclerosis.

F Mineral contents of bone

1 Normal bone

Calcium and phosphorus are the most important structural components of hydroxyapatite. Surrounding the crystal there is a halo of adsorbed water molecules and this halo is called the hydration shell. Present in the hydration shell either as solute or adsorbed are such ions as Mg^{++} Sr^{++} $CO_3^{=}$ Na^{+} Cl and citrate and Ca^{++} and PO_4 in some quantities (Frost 1962) Roughly 65 to 70 % of the dry substance of the bone consists of hydroxy apatite crystals (Glimcher 1959) The fatless dry weight of the bone of an adult consists of 26 4 % of calcium 11,3 % of phosphorus 0 18 to 0,6 % of sodium 0,39 of magnesium 0 094 to 0,270 % of fluorine (the amount grows with the age) 0,05 to 0,3 % of potassium 0 011 to 0 017 % of iron 0,0002 to 0 0048 % of copper 0 001 to 0,01 of lead 4 0 % of carbonate and 0 18 % of

chlorine (Documenta Geigy Wissenschaftliche Tabellen, 7 Aufl., 1968)

2. *Normal auditory ossicles and the labyrinthine capsule*

Karlsson et al. (1954) examined mineralization of the auditory ossicles by microradiographic methods and found that the mineral content is low around the haversian canal. In the different parts of the auditory ossicles, the relative mineral contents were remarkably different. Orlandini & Sberuini (1956) noted, also by microradiographic methods, significant variations in the mineral content of the auditory ossicles of persons at different ages. Maurer (1960) examined by chemical analysis the calcium and phosphorus contents of the auditory ossicles and temporal bone of 62 persons. He observed that the mineral contents of the auditory ossicles and labyrinthine capsule were significantly higher than those of the mastoid process and mastoid cortex. The values in men and women did not differ from each other neither did the values between different age groups. Maurer deduced that the organic substance of the auditory ossicles and labyrinthine capsule must differ from that of other bones because the mineral content of the ossicles is higher

Soifer et al. (1970a) examined the mineral contents of the auditory ossicles by neutron activation analysis. In the normal stapes, in an average 29.2±0.8 % was calcium and 11.1 ± 0.2 % phosphorus. Cortical bone samples were taken for control from the posterior wall of the external auditory meatus, and there was in an average 25.8±1.1 % of calcium and 8.2±0.6 % of phosphorus. Evens & Henkin (1969) examined whole mallei and incudes applying the monenergetic photon beam transmission. The stapes was not examined because of its small size. The mineral content of the malleus was significantly higher than that of the incus. No significant differences were noted in either of the bones between the right and left ears. No changes were observed, either in the mineral content of either of the bones in patients between the ages 17 and 60. After 60 however there was possibly decrease in the mineral content.

3. *The auditory ossicles and labyrinthine capsule in otosclerosis*

There are only few among the numerous investigations on otosclerosis which in a reliable way elucidate the possible effects of otosclerosis on the mineral content of the auditory ossicles and labyrinthine capsule. Although several investigators have reported different otosclerotic changes in the auditory ossicles as well (Covell 1940, Nager 1944, Lempert & Wolff 1949) it is a generally accepted view that these changes are secondary involving the stapedial footplate through ingrowth of the otosclerotic focus. Primary otosclerosis in the stapedial footplate is rather rare. On the other hand ossicular changes may develop because of impaired motility of the ossicular chain (Altmann 1965)

Ferreri & Coen (1951) examined the auditory ossicles of healthy persons and otosclerotic patients and found the calcium content to be the same in both groups. Employing electrolytic decalcification, Merlo & Sillingardi (1952) noted that the calcium content in the head of the malleus and incus was 21.6 % and correspondingly 24.8 % lower in otosclerotic than in healthy persons. Covell & Feinmesser (1959) found many different ill-defined changes in their series of 209 ossicles obtained at fenestration operations. Flor & Martinozzi (1960) also found several cases of osteoporosis and bone atrophy in the malleus and incus of otosclerotic patients.

Maurer (1961/62) compared the calcium and phosphorus contents in healthy and otosclerotic persons on one hand in the

ossicles and labyrinthine capsule and on the other hand in the mastoid cortex and mastoid process The mineral contents were at the same level in the mastoid cortex and mastoid process both in healthy and otosclerotic patients On the other hand the calcium and phosphorus contents of the ossicles and labyrinthine capsule were significantly lower in otosclerotic than healthy persons Maurer drew the conclusion that otosclerotic patients have more collagen fibrils in their ossicles and labyrinthine capsule than healthy persons. There were no differences in the mineral contents in the area of lamellar bone (mastoid cortex and mastoid process) on the other hand the differences were distinct in the area of fibrous bone (the auditory ossicles and labyrinthine capsule) between otosclerotic and healthy subjects Clarce (1964) carried out an electron microscopic study on 35 cases of otosclerotic stapes and divided the cases into three groups with the mineral content as a criterion Group 1 represented patients under 28 years of age with a history of progressive deafness for less than 3 years These patients showed some decalcification compared with normal stapes bone. Group 2 consisted of patients younger than 32 years with a history of impaired hearing for less than 3 years These cases were characterized by more marked demineralization. The patients on Group 3 were older than 32 years of age with a history of decreased hearing for more than 3 years They showed increased density indicating some degree of recalcification Röckert et al (1965) examined different parts of the stapes in otosclerotic patients by electron and fluorescence microscopy In mineralization very great individual variation was noted in the head of the stapes *some parts of it were* completely demineralized.

In 1967 Maurer strengthened the results of his earlier investigations by chemical analysis of the calcium and phosphorus contents in the ossicles and bony labyrinthine capsule and the mastoid cortex and mastoid process In healthy patients, the contents were higher in web-like bone (the ossicles and labyrinthine capsule) than in haversian bone (mastoid cortex and mastoid process) On the other hand in the web-like bone of otosclerotic patients the mineral contents were significantly lower than in the control group In haversian bone however there were no differences in the calcium and phosphorus contents between otosclerotic patients and healthy subjects. Maurer suggested *that the web-like bone of* otosclerotic patients contains more fibrils than normally

In their investigation on the role of fluorine in otosclerosis Linck et al (1967) observed that the normal footplate and crura have an equal amount of calcium per unit of weight as normal meatal bone On the other hand even a 100 % otosclerotic foot plate had less calcium than the healthy foot plate According to these investigators, a completely mature otosclerotic bone is unable to reach the high degree of mineralization which is characteristic of the labyrinthine capsule bone. They think however that the calcium content in otosclerotic and *meatal bone is at about the same level.* Garcia Ibañez (1968) suggested that the mineral content of otosclerotic bone is generally lower than that of the healthy stapes Evens and Henkin (1969) applied the monergetic photon beam transmission in examining the malleus and incus of otosclerotic patients The mineral content of the malleus was somewhat lower and that of the incus significantly lower in otosclerotic than in healthy subjects Soifer et al (1970a) examined calcium phosphorus zinc magnesium and sodium concentrations by neutron activation analysis in the stapes and cortical bone in otosclerotic and healthy persons No statistically significant differences were noted Soifer et al (1970b) used the same method *and did not either find* any statistically significant differences in

the calcium iodine, magnesium, chlorine, or sodium levels of the stapes and cortical bone of healthy and otosclerotic subjects.

The effect of fluoride on inactivation of the otosclerotic process has been investigated with great interest in recent years (Shambaugh & Scott 1964 Shambaugh & Petrovic 1967) In hydroxyapatite the hydroxy ion is replaced by sodium fluoride and thus is fluorapatite formed which is less soluble than normal hydroxyapatite (Arnold 1960) Fluorine once deposited in bone remains there for the life of the individual so that there is a steady increase in the fluorine content of the bones from childhood to old age (Smith et al. 1953) Linck et al. (1967) noted that the normal stapedial footplate and crura have the same amount of fluoride than the normal meatal bone. They also observed that the fluoride content of otosclerotic bone was even three times as high as that of the meatal bone. In their experiments on rats Petrovic & Shambaugh (1968) noted that sodium fluoride promoted bone calcification by decreasing bone resorption and stimulating calcium deposition. Shambaugh (1969) suggested that at its early stage, the otosclerotic focus consists of active areas poor in calcium. It is these areas that sodium fluoride influences.

ossicles and labyrinthine capsule and on the other hand in the mastoid cortex and mastoid process The mineral contents were at the same level in the mastoid cortex and mastoid process both in healthy and otosclerotic patients. On the other hand the calcium and phosphorus contents of the ossicles and labyrinthine capsule were significantly lower in otosclerotic than healthy persons Maurer drew the conclusion that otosclerotic patients have more collagen fibrils in their ossicles and labyrinthine capsule than healthy persons There were no differences in the mineral contents in the area of lamellar bone (mastoid cortex and mastoid process) on the other hand the differences were distinct in the area of fibrous bone (the auditory ossicles and labyrinthine capsule) between otosclerotic and healthy subjects Clarce (1964) carried out an electron microscopic study on 35 cases of otosclerotic stapes and divided the cases into three groups with the mineral content as a criterion Group 1 represented patients under 28 years of age with a history of progressive deafness for less than 3 years These patients showed some decalcification compared with normal stapes bone. Group 2 consisted of patients younger than 32 years with a history of impaired hearing for less than 3 years These cases were characterized by more marked demineralization The patients on Group 3 were older than 32 years of age with a history of decreased hearing for more than 3 years They showed increased density indicating some degree of recalcification Röckert et al (1965) examined different parts of the stapes in otosclerotic patients by electron and fluorescence microscopy In mineralization very great individual variation was noted in the head of the stapes some parts of it were completely demineralized.

In 1967 Maurer strengthened the results of his earlier investigations by chemical analysis of the calcium and phosphorus contents in the ossicles and bony labyrinthine capsule and the mastoid cortex and mastoid process In healthy patients, the contents were higher in web-like bone (the ossicles and labyrinthine capsule) than in haversian bone (mastoid cortex and mastoid process) On the other hand in the web-like bone of otosclerotic patients the mineral contents were significantly lower than in the control group In haversian bone however there were no differences in the calcium and phosphorus contents between otosclerotic patients and healthy subjects. Maurer suggested that the web-like bone of otosclerotic patients contains more fibrils than normally

In their investigation on the role of fluorine in otosclerosis Linck et al (1967) observed that the normal footplate and crura have an equal amount of calcium per unit of weight as normal meatal bone. On the other hand even a 100 % otosclerotic footplate had less calcium than the healthy footplate. According to these investigators a completely mature otosclerotic bone is unable to reach the high degree of mineralization which is characteristic of the labyrinthine capsule bone. They think, however that the calcium content in otosclerotic and meatal bone is at about the same level García Ibañez (1968) suggested that the mineral content of otosclerotic bone is generally lower than that of the healthy stapes. Evens and Henkin (1969) applied the monergetic photon beam transmission in examining the malleus and incus of otosclerotic patients The mineral content of the malleus was somewhat lower and that of the incus significantly lower in otosclerotic than in healthy subjects Soifer et al (1970a) examined calcium phosphorus zinc magnesium and sodium concentrations by neutron activation analysis in the stapes and cortical bone in otosclerotic and healthy persons No statistically significant differences were noted Soifer et al (1970b) used the same method and *did not either find* any statistically significant differences in

the calcium iodine, magnesium, chlorine, or sodium levels of the stapes and cortical bone of healthy and otosclerotic subjects.

The effect of fluoride on inactivation of the otosclerotic process has been investigated with great interest in recent years (Shambaugh & Scott 1964 Shambaugh & Petrovic 1967) In hydroxyapatite, the hydroxy ion is replaced by sodium fluoride and thus is fluorapatite formed, which is less soluble than normal hydroxyapatite (Arnold 1960) Fluorine once deposited in bone remains there for the life of the individual so that there is a steady increase in the fluorine content of the bones from childhood to old age (Smith et al. 1953) Linck et al (1967) noted that the normal stapedial footplate and crura have the same amount of fluoride than the normal meatal bone. They also observed that the fluoride content of otosclerotic bone was even three times as high as that of the meatal bone. In their experiments on rats Petrovic & Shambaugh (1968) noted that sodium fluoride promoted bone calcification by decreasing bone resorption and stimulating calcium deposition. Shambaugh (1969) suggested that at its early stage the otosclerotic focus consists of active areas poor in calcium. It is these areas that sodium fluoride influences.

ossicles and labyrinthine capsule and on the other hand in the mastoid cortex and mastoid process. The mineral contents were at the same level in the mastoid cortex and mastoid process both in healthy and otosclerotic patients On the other hand the calcium and phosphorus contents of the ossicles and labyrinthine capsule were significantly lower in otosclerotic than healthy persons. Maurer drew the conclusion that otosclerotic patients have more collagen fibrils in their ossicles and labyrinthine capsule than healthy persons. There were no differences in the mineral contents in the area of lamellar bone (mastoid cortex and mastoid process) on the other hand the differences were distinct in the area of fibrous bone (the auditory ossicles and labyrinthine capsule) between otosclerotic and healthy subjects Clarce (1964) carried out an electron microscopic study on 35 cases of otosclerotic stapes and divided the cases into three groups with the mineral content as a criterion Group 1 represented patients under 28 years of age with a history of progressive deafness for less than 3 years. These patients showed some decalcification compared with normal stapes bone Group 2 consisted of patients younger than 32 years with a history of impaired hearing for less than 3 years. IV Material and methods

A. Material

The material consists of bone specimens, which were collected in the Otolaryngological University Clinic Uni ersity of Turku Turku, Finland, in connection with operations for otosclerosis. The specimens were pieces of stapedial footplates including otosclerotic foci. Pieces of stapedial crura were included as well, and the head of the stapes in a few cases The specimens were taken from 250 patients in all of which 70 (174) were women and 30 % (76) men. The age of the patients aried from 7 to 64 years. The mean age in the whole series was 41 7 years the mean age of women being 43.3 years and of men 37.9 years (Table 1) A bone piece of the inner end of the posterior meatal wall was taken from 10 otosclerotic patients.

The control group consisted of 20 deceased patient with no history of impaired hearing. For the present investigation all auditory ossicles were collected from both ears. The group included 10 women and 10 men the age arying from 4 to 76 years. The mean age was 45.3 years in women 46.2 years and men 44 4 years.

Table 1 *Distribution of the material according to age and sex.*

41—50	56	22
51—60	43	11
61—70	4	1

B. Methods

1 General

The bone pec mens collected during the years 1960—1966 were kept in 10 formal ne n losed glass tubes. The specimens were put into clean glass tubes and cleaned twice with di t lled water and thereafter ... ater warming up ... This was made ... there was no crystallized formaline in the specimens and that they were also in other respects as clean as possible. The 1966—68 material was collected directly from operations and put dry in glass tubes. They were treated in the same way as the other specimens except that they were not kept in formaline

In a part of the otosclerotic samples a piece of bone was separated by a knife for further treatment. These pieces were extracted in the Soxhlet apparatus in 80 % ethylendiamine for eight hours and thereafter two more times in the Soxhlet apparatus in distilled water for eight hours. Then the samples were dried at +95°C for 24 hours. Thus it was possible to eliminate most of the organic material from the bone pieces. Some of the samples which were treated with ethylendiamine were, however broken down almost completely during the process. A part of the control material was treated as well in the Soxhlet apparatus in 80 % ethylendiamine.

2. X-ray crystallographic examination

For the examination of the crystalline structure of the bone x-ray diffraction was employed.

III The aim of the study

The aim of the present study is to answer the following questions

1 What is the crystalline structure like in healthy auditory ossicles and does it differ from the crystalline structure of normal human bone?

2 What is the crystalline structure of otosclerotic bone like compared with that of normal human bone?

3 How are the bone crystals oriented in normal ossicles and otosclerotic bone?

4 At what stage of otosclerosis do the possible changes in the crystalline structure appear?

5 Does the mineral content of the otosclerotic focus differ from that of the normal stapedial footplate?

IV Material and methods

B. Methods

1 General

The bone specimens collected during the years 1960—1966 were kept in 10 formal ne in closed glass t bes. The specimens w e put into clean glass tubes and cleaned twice with distilled water and thereafter once more with distilled water warming up to +60°C for three hours. This was made in order to secure that there was no crystallized formaline in the specimens and that they were also in other respects as clean as possible. The 1966—68 material was collected directly from operations and put dry in glass tubes. They were treated in the same way as the other specimens except that they were not kept in formaline.

In a part of the otosclerotic samples, a piece of bone was separated by a knife for further treatment. These pieces were extracted in the Soxhlet apparatus in 80 % ethylendiamine for eight hours and thereafter two more times in the Soxhlet apparatus in distilled water for eight hours. Then the samples were dried at +95°C for 24 hours. Thus it was possible to eliminate most of the organic material from the bone pieces. Some of the samples which were treated with ethylendiamine were however broken down almost completely during the process. A part of the control material was treated as well in the Soxhlet apparatus in 80 ethylendiamine.

2. X-ray crystallographic examination

For the examination of the crystalline structure of the bone x-ray diffraction was employed.

III The aim of the study

The aim of the present study is to answer the following questions

1 What is the crystalline structure like in healthy auditory ossicles and does it differ from the crystalline structure of normal human bone?

2 What is the crystalline structure of otosclerotic bone like compared with that of normal human bone?

3 How are the bone crystals oriented in normal ossicles and otosclerotic bone?

4 At what stage of otosclerosis do the possible changes in the crystalline structure appear?

5 Does the mineral content of the otosclerotic focus differ from that of the normal stapedial footplate?

phosphorus determinations the samples were dissolved by nitric acid (Merck, p.a.) and diluted to suitable volume. The calcium and magnesium analyses were carried out by an atom absorption spectrophotometer (Techtron AA-5)

The statistical significances were counted by Student's t test.

The first method was the Debye Scherrer method (Cullity 1956) The diameter of the Debye-Scherrer camera was 114 6 mm. It was used Ni filtered CuK radiation (40 kV and 16 mA) The exposure time was two hours

Preparing of the control samples for the Debye-Scherrer method was done with a file by which certain parts of the ossicles were filed and the powder was packed into Debye Scherrer capillaries with a diameter of 0.2 mm. The ends of the tubes were closed by heating them in a flame. The otosclerotic samples were usually so small that powder samples were not easy to make. That is why bone needles were used which were made with a knife under the operating microscope. Both the glass capillaries and bone needles were fixed in the Debye-Scherrer camera with wax. The wax was not allowed to come under primary radiation. The Debye-Scherrer patterns were measured by a microphotometer (Jarrel Ash Company Mass USA)

For examination of the orientation of bone crystals the Laue transmission method was employed (Cullity 1956) It was used Ni filtered CuK radiation (50 kV and 16 mA) The distance from the specimen to the film was 40 mm and the exposure time varied from one to three hours depending on the thickness of the sample.

Preparing of the control samples for the Laue transmission method was done with a file by which bone plates of the thickness of 200 to 400 μm were made of the ossicles The thickness was defined by a micrometer In the investigation of the otosclerotic material bone sections made for the microradiographic examination were used

3 *Microradiographic examination*

The developmental stage of the otosclerotic focus was examined by microradiographic methods. The bone pieces to be examined were embedded in methylmethacrylate The preparations were sawn about 1 mm thick by a rotating saw The sections were manually ground about 50 to 100 μm thick, and the final grinding was performed by polishing the section with a special glass plate in alcohol The thickness was measured by a micrometer

Soft roentgen contact microradiography was used in the present investigation. It was used Ni filtered CuK radiation (20 kV and 16 mA) Target to film distance was 30 cm. The exposure time was two to six hours. Kodak Maximum Resolution plates were used and developing took place in a Kodak Universal Developer The absorption of x rays was measured by a microscope photometer (Microskop-Photometer MPE, Leitz)

4 *Quantitative mineral analysis*

Neutron activation analysis and atom absorption spectrophotometry were applied. The bone samples were extracted in diethyl ether for 48 hours and thereafter in acetone for 24 hours. Then the samples were dried at +95°C for 72 hours After this, they were cooled for 15 minutes in an exsiccator and weighed (Electromicrobalance EMB-1 Research & Industrial Instruments Company London) The samples and sodium and phosphorus comparative standards were irradiated for two hours in the reactor (Triga Mark II the neutron flux of 2×10^{12} n/cm s) After a delay of 24 hours the γ spectra of the samples and sodium comparative standards were measured and on the basis of the results sodium determinations were carried out The 3 x 3 NaJ (Tl) crystal and 128-channel pulse height analyser (ND-110) were used for γ measurements. After 48 hours the phosphorus contents of the samples were determined on the basis of β measurements The half life measurements showed that the half lives of the activities of bone samples and phosphorus comparative standards were identical After

phosphorus determinations, the samples were dissolved by nitric acid (Merck, p.a.) and diluted to suitable volume. The calcium and magnesium analyses were carried out by an atom absorption spectrophotometer (Techtron AA 5)

The statistical significances were counted by Student's t test.

The first method was the Debye Scherrer method (Cullity 1956) The diameter of the Debye-Scherrer camera was 114 6 mm It was used Ni filtered CuK radiation (40 kV and 16 mA) The exposure time was two hours

Preparing of the control samples for the Debye-Scherrer method was done with a file by which certain parts of the ossicles were filed, and the powder was packed into Debye-Scherrer capillaries with a diameter of 0.2 mm The ends of the tubes were closed by heating them in a flame The otosclerotic samples were usually so small that powder samples were not easy to make That is why bone needles were used which were made with a knife under the operating microscope Both the glass capillaries and bone needles were fixed in the Debye Scherrer camera with wax. The wax was not allowed to come under primary radiation The Debye-Scherrer patterns were measured by a microphotometer (Jarrel Ash Company Mass. USA)

For examination of the orientation of bone crystals the Laue transmission method was employed (Cullity 1956) It was used Ni-filtered CuK radiation (50 kV and 16 mA) The distance from the specimen to the film was 40 mm and the exposure time varied from one to three hours depending on the thickness of the sample

Preparing of the control samples for the Laue transmission method was done with a file by which bone plates of the thickness of 200 to 400 μm were made of the ossicles. The thickness was defined by a micrometer In the investigation of the otosclerotic material bone sections made for the microradiographic examination were used.

3 Microradiographic examination

The developmental stage of the otosclerotic focus was examined by microradiographic methods The bone pieces to be examined were embedded in methylmethacrylate. The preparations were sawn about 1 mm thick by a rotating saw The sections were manually ground about 50 to 100 μm thick, and the final grinding was performed by polishing the section with a special glass plate in alcohol The thickness was measured by a micrometer

4 Quantitative mineral analysis

Neutron activation analysis and atom absorption spectrophotometry were applied The bone samples were extracted in diethyl ether for 48 hours and thereafter in acetone for 24 hours. Then the samples were dried at +95°C for 72 hours After this they were cooled for 15 minutes in an exsiccator and weighed (Electromicrobalance EMB-1 Research & Industrial Instruments Company London) The samples and sodium and phosphorus comparative standards were irradiated for two hours in the reactor (Triga Mark II the neutron flux of 2×10^{12} n/cm²s) After a delay of 24 hours the γ spectra of the samples and sodium comparative standards were measured and on the basis of the results sodium determinations were carried out The 3 x 3 NaJ (Tl) crystal and 128-channel pulse height analyser (ND-110) were used for γ measurements After 48 hours the phosphorus contents of the samples were determined on the basis of β measurements. The half life measurements showed that the half-lives of the activities of bone samples and phosphorus comparative standards were identical. After

chain, and the direction of the bone plates to their original location was varying. The total of the bone plates was thus 40

The Laue patterns of the bone plates were generally distinct. The bone crystal orientation was best seen in strong 002 reflection. The bone crystals were arranged parallelly with collagen fibrils. In case the c-axes of the bone crystals are approximately perpendicular to the x-ray beam distinct arcing is seen in the 002 reflection as a sign of preferred crystal orientation. In the handle of the malleus the crystals were generally arranged longitudinally with the handle. This was true of the long crus of the incus as well. In the anterior crus of the stapes the crystals were most often parallel with the crus and in the stapedial footplate, they were mostly in line with the edge of the footplate. In the stapedial footplate there was, however great variation in the bone crystal orientation.

2 *Otosclerotic material*

a. The Debye-Scherrer method

All otosclerotic bone samples in the series were examined by the Debye-Scherrer method. Table 2 shows the distribution of the sexes in the material and the mean age of the patients at the time of the operation. The samples examined were collected from 250 patients in all.

After preliminary treatment the bone ieces were examined under an operating microscope. The aim was to find out what *part of the stapes the sample represented*. In most of the samples the original location of the bone piece in the stapes could be found out on the basis of morphological characteristics. In some cases the sample was a whole stapes, from which the wanted part was taken for examination. The general attempt was to choose the part of the bone which morphologically seemed to be most otosclerotic. The samples were divided roughly into three groups A. the sample represented the posterior part of the stapedial footplate including otosclerotic foci B the sample represented the anterior part of the stapedial footplate including otosclerotic foci a distinct separate otosclerotic focus was also included in this group C the sample represented the crus of the stapes (but not the base of the crus) or the head of the stapes. In some cases, the origin of the sample was not quite certain and in these cases the sample was left out. The meaning of this rough division was to localize the bone piece in the otosclerotic stapes.

The total of the investigation material consisted of 20 % (50) of A samples of 75 (187) of B samples and of 5 % (13) of C samples. The low figure of the C samples is explained by the fact that these

A. X ray crystallographic examination

1 Control material

a. The Debye-Scherrer method

For the crystallographic study of normal ossicles the ossicles of five women and five men belonging to the control group were chosen After the preliminary treatment powder samples were made by a file of the following objects 1 head of the malleus 2 manubrium of the malleus 3 body of the incus 4 long crus of the incus 5 head of the stapes 6 stapedial footplate (posterior) 7 stapedial footplate (anterior) 8 external auditory meatus (the inner end of the posterior wall) Ten samples were thus obtained of each object Making of the samples of the malleus and incus was relatively easy but treating the stapes was more difficult It is so brittle that it tended to break while filing it and in addition the stapes is poor in bony material The bone powder of the stapedial footplate was prepared from the base of both crura

Eighty Debye-Scherrer powder patterns were made in all of the normal ossicular chain and posterior wall of the external auditory meatus. Distinct diffraction pat terns were obtained of every sample All diffraction patterns were identical and they completely correspond to those of normal bone i.e. hydroxyapatite presented in th pertinent literature (Carlström 1955)

Most of the diffraction patterns were photometred *The intensity curves perfectly* corresponded to the curves of the diffraction patterns of normal bone.

In order to eliminate the disturbing back ground scattering caused by the organic component of the bone as carefully as possible a part of the normal ossicular chain was treated in the Soxhlet apparatus in 80 % ethylendiamine. Of the bony material thus obtained two powder samples were made of each of the eight objects mentioned above. Thus the diffraction lines became nar rower and sharper so that it was possible to observe even minor changes in the patterns. Even these Debye-Scherrer patterns were photometred Neither in these technically better diffraction patterns were any dif ferences from the pattern of normal hydr oxyapatite.

On the basis of the examinations reported above it is suggested that there are no crystalline structures in the normal ossicular chain and temporal bone (external meatus) that examined by the Debye-Scherrer meth od would differ from the crystalline struc ture of normal human bone

b The Laue transmission method

For the study of crystal orientation in normal auditory ossicles ossicles of five female and five male controls were chosen Thin bone plates were made of the cleaned ossicles by a file The thickness of the bone plates was generally 200 μm but some of the plates were as thick as 400 μm In these cases the exposure time was correspondingly made longer Bone plates were prepared *from the following objects 1* manubrium of the malleus 2. long crus of the incus 3 anterior crus of the stapes 4 stapedial footplate (anterior) When making the preparations the direction of the prepara tion plate in relation to its original location was known Thus it was possible to draw conclusions of crystal orientation in the original part of the ossicl T n pr parations were made of each part of the ossicular

chain, and the direction of the bone plates to their original location was varying. The total of the bone plates was thus 40.

The Laue patterns of the bone plates were generally distinct. The bone crystal orientation was best seen in strong 00'2 reflection. *The bone crystals were arranged parallelly with collagen fibrils.* In case the c-axes of the bone crystals are approximately perpendicular to the x-ray beam, distinct arcing is seen in the 00'2 reflection as a sign of preferred crystal orientation. In the handle of the malleus the crystals were generally arranged longitudinally with the handle. *This was true of the long crus of the incus* as well. In the anterior crus of the stapes, the crystals were most often parallel with the crus, and in the stapedial footplate they were mostly in line with the edge of the footplate. In the stapedial footplate there was, however great variation in the bone *crystal orientation.*

2. *Otosclerotic material*

a. The Debye-Scherrer method

All otosclerotic bone samples in the series were examined by the Debye-Scherrer method. Table 2 shows the distribution of the sexes in the material and the mean age of the patients at the time of the operation. The samples examined were collected from 250 patients in all.

After preliminary treatment, the bone pieces were examined under an operating microscope. mean age at the time of the operation was 42.4 years in this group. Figure 7 presents some diffraction patterns interpreted to represent the amorphous structure. Diffraction lines typical of hydroxyapatite are lacking for the most part. A photometer curve of the Debye-Scherrer pattern in Figure 7 (c) is seen in Figure 8. The figure presents a typical x-ray intensity curve of amorphous substance (Cullity 1956).

The total figure of samples with a crystalline structure deviating from the structure of normal hydroxyapatite was thus 25 % (62) in all. Of these, 74 % (46) were taken from women and 26 % (16) from men. The mean age of all abnormal cases was 41.6 years.

When the obtained crystalline structure types of the otosclerotic bone are analysed according to the *original site of the sample* in the stapes it is noted that 19 % (36) of the samples with normal crystalline *structure* belonged to Group A (the poste-

Table 4 *The results of the Debye-Scherrer examination*

Samples from	Normal crystalline structure %	No	Abnormal crystalline structure %	No.	Amorphous structure %	No.	Abnormal plus Amorphous %	No.
Women	68	(128)	83	(15)	70	(31)	74	(46)
Men	32	(60)	17	(3)	30	(13)	26	(16)

samples were examined only in case the stapedial footplate or a distinct otosclerotic focus was not available (Table 3) If the material was sufficient several Debye-Scherrer patterns were made of the stapes of the same patient alternating somewhat however the part from which the sample was taken Generally repeated photography gave a similar pattern but in some cases deviations from earlier photographs were noted. In these cases the deviating Debye-Scherrer pattern only was included For analysing the results the diffraction patterns of the otosclerotic material were compared with the diffraction pattern of normal hydroxyapatite. All diffraction patterns that were or were suspected to be different from normal were measured by the photometer Thereafter the Debye Scherrer patterns were divided into three main groups 1 Normal crystalline structure the Debye-Scherrer pattern is identical with the pattern of normal hydroxyapatite 2 Abnormal crystalline structure the Debye-Scherrer pattern deviates more or less from the pattern of normal hydroxyapatite The abnormality may e.g be deviation of some of the diffraction lines from its normal location strengthening or weakening of the relative intensity of the diffraction line or appearance of a new additional diffraction line 3 Amorphous structure no well-defined intensity maxima are noted in the Debye-Scherrer pattern but only diffuse and broad lines Dividing the results into three groups only is very rough because the limits between the different groups are at least partly diffuse. The division was however done in order to make the analysis of the results easier

Table 4 shows the distribution of the otosclerotic samples into different structural types on the basis of the Debye-Scherrer examination Seventy five per cent (188) of the 250 samples examined had a diffraction pattern that was considered normal. Of these samples 68 % (128) were taken from women and 32 % (60) from men The mean age at the time of the operation was 41 7 years in this group Figure 2 shows three Debye-Scherrer diffraction patterns regarded as normal and in Figure 3 the corresponding normal photometer curve is seen A diffraction pattern interpreted abnormal was found in 7 % (18) of the samples Of these samples 83 % (15) were taken from women and 17 % (3) from men In this group the mean age at the time of the operation was 39 4 years Figure 4 shows some Debye Scherrer diffraction patterns which have been considered to differ from the pattern of normal hydroxyapatite Attention must be paid to the fact that there are diffraction patterns of several different types In Figure 5 an intensity curve of the Debye-Scherrer pattern of Figure 4 (d) is seen and correspondingly Figure 6 presents the photometer curve of the Debye-Scherrer pattern seen in Figure 4 (g) A structure considered amorphous was noted in 18 % (44) of the samples of these 70 (31) wer from women and 30 % (13) from men Th

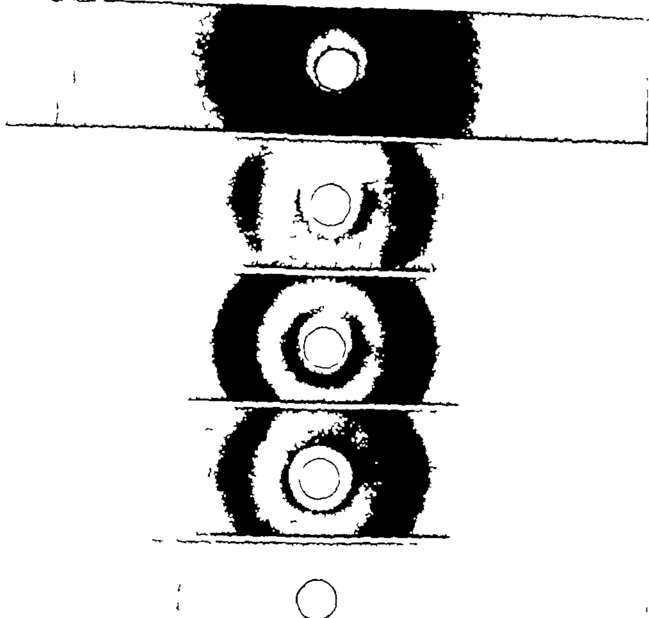

Fig 7 Debye-Scherrer diffraction patterns of otosclerotic bone. The patterns (a—e) indicate *amorphous structure*.

Group B and none to Group C Examined by the Debye-Scherrer method the crystal line structure of the bone was normal in all cases in the crura and head of the stapes (Table 5)

Since it is generally accepted that otosclerotic changes do not occur in upper parts of the crura or in the head of the stapes (≈Group C) samples belonging to Group C can be left out Then the percentages of the crystalline structure different from normal hydroxyapatite become higher Table 6 shows that samples in the groups A and B were 237 in all. Of these 73 % (175) were considered to represent the structure of normal hydroxyapatite The abnormal crystalline structure was noted in 8 % (18) of the samples, and an amorphous structure in 19 % (44) of the samples. Twenty seven per cent (62) of these samples belonging to

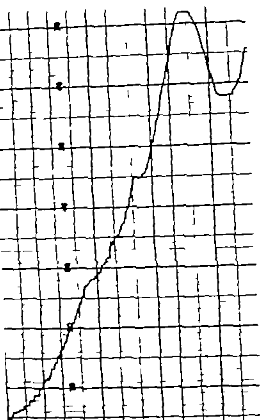

Fig. 8. Intensity curve of the Debye-Scherrer diffraction pattern in Fig. 7 (c). Typical curve of amorphous substance.

groups A and B were shown to have a structural deviation from normal hydroxyapatite.

Table 6. Distribution of the result of the Debye-Scherrer examination. Only the stapedial footplate is included.

Crystalline structure	%	No.
Normal	73	(175)
Abnormal	8	(18)
Amorphous	19	(44)
Abnormal plus Amorphous	27	(62)
Total	100	(237)

Table 7. Distribution of the results of the Debye-Scherrer examination. Sixty samples extracted by ethylendiamine were included.

Crystalline structure	%	No.
Normal	85	(51)
Abnormal	12	(7)
Amorphous	3	(2)
Abnormal plus Amorphous	15	(9)
Total	100	(60)

In order to make the grouping of the samples more reliable a part of the samples were extracted in ethylendiamine in the Soxhlet apparatus after the native photographing described above. These samples were 26 % (66) of the total material, and of these 66 65 % (43) were taken from women and 35 % (23) from men. During the treatment six samples were broken down so that the Debye-Scherrer patterns were obtained of 60 samples. A normal diffraction pattern was noted in 85 % (51) of the samples. The abnormal crystalline structure was found in 12 % (7) of the samples and amorphous structure in 3 % (2). Structures deviating from normal hydroxyapatite were thus in 15 % (9) in all (Table 7). It is probable that most of the samples that were broken down during the ethylendiamine extraction belonged to amorphous cases. Most of the diffraction patterns obtained from samples treated with ethylendiamine were identical with earlier results. The technically better Debye-Scherrer patterns thus obtained were in three cases considered abnormal instead of regarding them as normal on the basis of native photographing.

A piece of bone from the medial part of the posterior meatal wall of 10 otosclerotic patients were also examined by making Debye-Scherrer powder patterns of them. All diffraction patterns thus obtained were

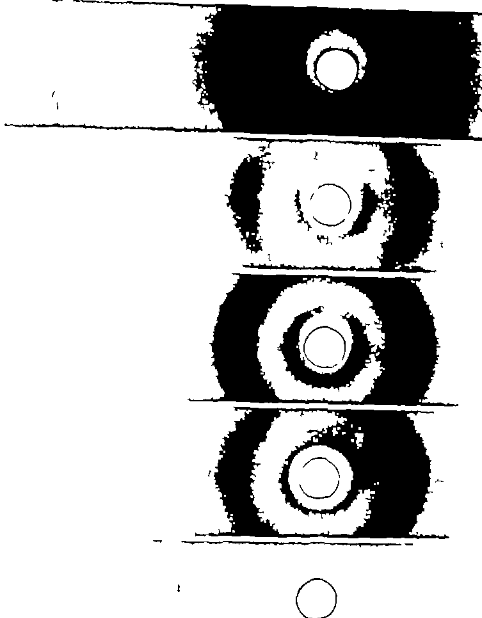

Fig 7 Debye-Scherrer diffraction patterns of otosclerotic bone. The patterns (a—c) indicate amorphous structure.

Group B and none to Group C Examined by the Debye-Scherrer method the crystal line structure of the bone was normal in all cases in the crura and head of the stapes (Table 5)

Since it is generally accepted that otosclerotic changes do not occur in upper parts of the crura or in the head of the stapes (=Group C) samples belonging to Group C can be left out. Then the percentages of the crystalline structure different from normal hydroxyapatite become higher Table 6 shows that samples in the groups A and B were 237 in all Of these 73 % (175) were considered to represent the structure of normal hydroxyapatite. The abnormal crystalline structure was noted in 8 % (18) of the samples, and an amorphous structure in 19 % (44) of the samples Twenty seven per cent (62) of these samples belonging to

Table 9 *Results of the Laue examination.*

Samples from	Preferred orientation		No preferred orientation		Indistinct Laue pattern (amorphous)	
	%	No.	%	No.	%	No.
Women	67	(8)	76	(26)	75	(3)
Men	33	(4)	24	(8)	25	(1)
Total	100	(12)	100	(34)	100	(4)

Table 9 shows the results of the crystal orientation investigation. Out of the 50 examined samples in 24 % (12) a more or less clearly preferential bone crystal orientation was seen. Sixty-seven per cent (8) of these were taken from women and 33 % (4) of men. Figure 9 presents a Laue pattern, in which distinct intensity maxima and minima are seen in strong 00 2 reflection as a sign of preferred bone crystal orientation No orientation, according to the Laue pattern was seen in 68 % (34) of the samples of which 76 % (26) were from women and 24 % (8) from men. In the Laue pattern in Figure 10 the arcing phenomenon is not seen, and this means that the bone crystals in this sample are not clearly oriented. Four samples did not give a clear diffraction photograph at all, but only a typical pattern of the amorphous structure.

Table 10. *Distribution of the results of the Laue examination. The crystalline structures are based on the Debye-Scherrer examination.*

Bone crystal orientation	Normal crystalline structure		Abnormal crystalline structure	
	%	No.	%	No.
Preferred orientation	25	(10)	20	(2)
No preferred orientation	65	(26)	80	(8)
Indistinct Laue pattern (amorphous)	10	(4)	—	(—)
Total	100	(40)	100	(10)

The distribution of bone crystal orientation into normal or abnormal cases on the basis of the Debye-Scherrer examination is seen in Table 10 In the samples with normal crystalline structure in 25 % (10) orientation was noted, in 65 % (26) there was no preferred orientation and 10 % (4) gave a diffraction pattern typical of the amorphous structure. On the other hand in 80 % (8) of the samples with the abnormal crystalline structure, no perferred orientation was observed.

B. Microradiographic examination

Fifty bone pieces were arbitrarily selected from the otosclerotic cases for the microradiographic examination. Yet, all samples belonged to Group B because the samples were chosen to be as otosclerotic as possible for this examination. Table 11 shows the composition of the material. Another principle for selection was to include 30 bone pieces with normal crystalline structure 10 with abnormal crystalline structure and 10 with amorphous structure. Of the first mentioned 77 % (23) cases were from women and 23 % (7) from men, in the second group 80 % (8) were from women and 20 % (2) from men and in the last mentioned group 0 % (7) were from women and 30 % (3) from men. Thus, in the microradiographic examination 76 % (38) of the samples were from women and 24 % (12) from men. The mean age of the whole group was 41 7 years at the time of the operation in women 42.9 and in men 38.1 years.

The original aim of the microradiographic examination was to determine the quantitative mineral contents in otosclerotic bone samples by the soft roentgen contact microradiographic technique. For this reason, a reference system made of aluminium foils was placed next to the bone sections during

identical with the diffraction pattern of hydroxyapatite.

b The Laue transmission method

In the crystal orientation examination of otosclerotic samples methylmethacrylate sections prepared for microradiographic examination were used. These sections could be fixed in the Laue camera without special arrangements. Now it was not, however possible to know in which direction the thin section was originally cut from the bone. That is why the present author could only find out whether the bone crystals were oriented at all The direction of the orientation could thus not be elucidated.

Samples for the crystal orientation study were chosen partly arbitrarily from the original samples All selected bone pieces belonged to Group B in other words they represented the anterior part of the otosclerotic footplate or a clear separate otosclerotic focus Forty samples with the normal crystalline structure were taken Out of these samples 73 % (29) were from women and 27 % (11) from men. In addition 10 samples with the abnormal crystalline structure were included and 80 % (8) of these were from women and 20 % (2) from men The number of bone samples thus totalled up to 50 Samples with the amorphous structure according to the Debye-Scherrer investigation were all excluded (Table 8)

Table 8. *Distribution of the bone material in the Laue examination. The crystalline structures are based on the Debye-Scherrer examination.*

Samples from	Normal crystalline structure		Abnormal crystalline structure	
	%	No.	%	No.
Women	73	(29)	80	(8)
Men	27	(11)	20	(2)
Total	100	(40)	100	(10)

The Laue patterns were divided into two groups 1 bone crystals with more or less preferential orientation and 2 bone crystals with no preferred orientation. If the arcing phenomenon was not noted in the 002 reflection the samples were counted to the second group

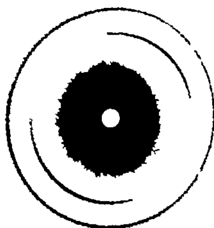

Fig 9 Laue transmission pattern of otosclerotic bone. Clear arcing in 002 reflection as a sign of preferred bone crystal orientation.

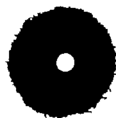

Fig 10 Laue transmission pattern of otosclerotic bone. No clear arcing in 002 reflection showing lack of preferred bone crystal orientation.

Table 9 *Results of the Laue examination*

Samples from	Preferred orientation		No preferred orientation		Indistinct Laue pattern (amorphous)	
	%	No.	%	No.	%	No.

Total	100	(40)	100	(10)

photograph at all but only a typical pattern of the amorphous structure.

The distribution of bone crystal orientation into normal or abnormal cases on the basis of the Debye-Scherrer examination is seen in Table 10 In the samples with normal crystalline structure, in 25 % (10) orientation was noted in 65 % (26) there was no preferred orientation and 10 (4) gave a diffraction pattern typical of the amorphous structure. On the other hand, in 80 % (8) of the samples with the abnormal crystalline structure no perferred orientation was observed.

B. Microradiographic examination

Fifty bone pieces were arbitrarily selected from the otosclerotic cases for the microradiographic examination. Yet, all samples belonged to Group B because the samples were chosen to be as otosclerotic as possible for this examination. Table 11 shows the composition of the material. Another principle for selection was to include 30 bone pieces with normal crystalline structure, 10 with abnormal crystalline structure and 10 with amorphous structure. Of the first mentioned, 77 % (23) cases were from women and 23 % (7) from men, in the second group 80 % (8) were from women and 20 % (2) from men and in the last mentioned group 70 % (7) were from women and 30 % (3) from men. Thus, in the microradiographic examination, 76 % (38) of the samples were from women and 24 (12) from men. The mean age of the whole group was 41.7 years at the time of the operation, in women 42.9 and in men 38.1 years.

The original aim of the microradiographic examination was to determine the quantitative mineral contents in otosclerotic bone samples by the soft roentgen contact microradiographic technique. For this reason, a reference system made of aluminium foils was placed next to the bone sections during

Fig 11 Microradiograph representing the fourth developmental stage of otosclerotic bone. The marrow spaces are greatly enlarged. Curving bone trabeculae join each other and there are a great number of osteocytic lacunae irregular in shape. The typical honeycomb-like structure is seen in some places. In the Debye-Scherrer examination, this sample gave a diffraction pattern typical of amorphous structure.

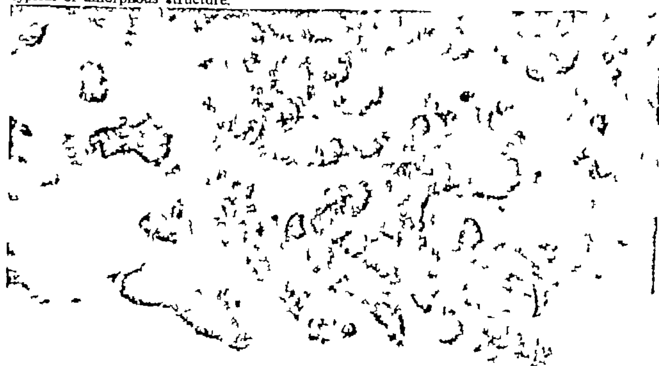

Fig. 12 Microradiograph representing the third developmental stage of otosclerotic bone. Osteocytic lacunae are fewer and the trabeculae thicker The marrow spaces are more scarce than in the fourth stage focus. In the Debye-Scherrer examination a diffraction pattern showing abnormal crystalline structure was obtained of this sample

Fig 13 Microradiograph, which represents the second developmental tage of otosclerotic bone. The marrow spaces are more scarce than t the third stage. The trabeculae are thick, and the osteocytic lacunae are fewer and more regular The crystalline structure examination revealed abnormal structure in this sample.

I g 14 Microradiograph representing the otosclerotic focus at the first developmental stage. Thi tage is the most matu e. A distinct tendency to lamellar more regular structure is noted. The tructure as whole is more compact. The number of osteocytic lacunae is only somewhat greater than normally I the Debye Scherrer examination, this sample gave a diffraction pattern of normal rystalline structure

Fig 11 Microradiograph representing the fourth developmental stage of otosclerotic bone. The marrow spaces are greatly enlarged. In the Debye-Scherrer examination, a diffraction pattern showing abnormal crystalline structure was obtained of this sample.

Fig 13. Microradiograph, which represents the second developmental stage of otosclerotic bone. The marrow spaces are more scarce than at the third tage. The trabeculae are thick, and the osteocytic lacunae are fewer and more regular The cry talline structure examination revealed abnormal structure in this sample.

I g 14 Microradiograph representing the tosclerotic focus at the first developmental stage. Thi stage is the most inact A distinct tendency to lamellar more regular structure is noted The tructure as a whole is more compact. The number of osteocytic lacunae is only somewhat greater than normally I the Debye Scherrer examination this sample gave diffraction pattern of normal cry talline tructure.

Table 11 *Distribution of the bone material in the microradiographic examination according to the crystalline structure.*

Samples from	Normal crystalline structure		Abnormal crystalline structure		Amorphous structure	
	%	No	%	No	%	No
Women	77	(23)	80	(8)	70	(7)
Men	23	(7)	20	(2)	30	(3)
Total	100	(30)	100	(10)	100	(10)

the exposure The thickness of this aluminium stepwedge was 15 30 45 150 μm Thereafter the microradiographs were measured by photometry and the mineral contents of the bone pieces were thus attempted to be determined quantitatively A great margin for errors was however revealed and the author had to give up any conclusions. Still it seemed evident that bone samples which had amorphous structure according to the Debye-Scherrer method contained less minerals than the samples with normal or abnormal crystalline structure

On the basis of the microradiographs obtained the otosclerotic samples were divided into different developmental stages Four different stages were grouped according to Henner et al (1960) and Garcia Ibañez (1968) The meaning of the grouping was to find out at what developmental stage of otosclerosis abnormal crystalline structures appear It must be kept in mind however that the otosclerotic samples in the present investigation were small in size, which caused difficulties.

Table 12. *Results of the microradiographic examination. The developmental stages of otosclerotic bone according to the crystalline structure.*

Developmental stage	Normal crystalline structure		Abnormal crystalline structure		Amorphous structure	
	%	No	%	No	%	No
IV	30	(9)	30	(3)	100	(10)
III	30	(9)	40	(4)	—	(—)
II	17	(5)	20	(2)	—	(—)
I	23	(7)	10	(1)	—	(—)
Total	100	(30)	100	(10)	100	(10)

Table 12 shows the results of the microradiographic grouping The results reveal that the samples with amorphous structure represent the youngest most active otosclerotic foci. On the other hand, abnormal crystalline structures may apparently occur at all developmental stages of the otosclerotic process. Of the total number of the samples 44 % (22) belonged to the fourth 26 % (13) to the third 14 % (7) to the second and 16 % (8) to the first developmental stage

C. Quantitative mineral analysis

1 Control material

After preliminary treatment a small bone piece was taken from the anterior part of the footplate of the control stapedes. The anterior part was chosen for the reason that a control material as good as possible was wanted for the otosclerotic material which mostly contained samples of the anterior part of the stapedial footplate. The number of the control samples was 20 The samples were dried to constant weight and weighed whereafter sodium and phosphorus contents were determined quantitatively by neutron activation analysis and calcium and magnesium contents by atom absorption spectrophotometry

Table 13 shows the constant weight and calcium phosphorus sodium and magnesium contents of each sample in mg/100 mg bone. The table reveals that the average content of calcium in the normal stapedial footplate is 30.28 of phosphorus 15 96 of sodium 0 43 and of magnesium 0.34

Table 13. *Ca, P Na and Mg contents of normal stapedial footplate (the anterior part) in mg/100 mg bone.*

	Abnormal otos. bone	0.23	0.01			

ingly the phosphorus content of this kind of otosclerotic bone (13.87) is significantly lower than that of normal stapedial bone (15.96) ($p<0.01$). Between the sodium contents of normal stapedial bone (0.43) and otosclerotic bone with normal crystalline structure (0.41) no statistically significant difference was noted. On the other hand, the magnesium content of otosclerotic bone (0.26) is nearly significantly lower than that of normal stapedial bone (0.34) ($p<0.05$).

um contents of otosclerotic samples with normal crystalline structure in mg/100 mg bone The average content of calcium in this group is 25 85 of phosphorus 13.87 of sodium 0 41 and of magnesium 0.26

Table 16 shows the constant weights and calcium phosphorus sodium and magnesium contents of otosclerotic samples with abnormal crystalline structure in mg/100 mg bone In samples with abnormal crystal line structure the average content of calcium was 24 70 of phosphorus 14.27 of sodium 0.36 and of magnesium 0.23

Table 17 shows the constant weights and calcium phosphorus sodium and magnesium contents of otosclerotic samples with amorphous structure in mg/100 mg bone. In the samples with amorphous structure the average content of calcium was 18.24 of phosphorus 10.51 of sodium 0.35 and of magnesium 0 18

In Table 18 a comparison is carried out between the mineral contents of normal stapedial bone and otosclerotic stapedial bone with normal crystalline structure The calcium content of otosclerotic bone (25 85) is significantly lower than that of normal stapedial bone (30.28) ($p<0.01$) Correspond

When comparing the mineral contents of normal stapedial bone and otosclerotic stapedial bone with abnormal crystalline structure the calcium content in the last mentioned (24 70) is observed to be significantly lower than in the first mentioned (30.28) ($p<0.01$) On the other hand, the phosphorus content in the otosclerotic bone (14.27) does not statistically differ from that of normal stapedial bone (15 96) ($p<0\ 1$) In the sodium contents there is no statistically significant difference in this group either The magnesium content of otosclerotic bone (0.23) is again significantly lower than in the normal stapedial bone (0.34) ($p<0\ 01$) (Table 19)

In Table 20 a comparison is presented between the mineral contents of normal stapedial bone and otosclerotic stapedial bone with amorphous structure The calcium content is highly significantly lower in the otosclerotic group (18.24) than in the control group (30.28) ($p<0\ 001$) The same is true about the phosphorus content (10.51 and 15 96 respectively) ($p<0\ 001$) There is no statistically significant difference in th sodium contents but the magnesium content again (0 18) is highly significantly lower than in the normal bone (0.34) ($p<0\ 001$)

No statistically significant differences are noted between any mineral contents of otosclerotic bone with normal and with abnormal crystalline structures (Table 21)

In Table 22 there is a comparison between the mineral contents of otosclerotic stapedial bone with normal crystalline structure and with amorphous structure The calcium content is highly significantly lower in the amorphous *(18.24) than in normal (25.85)* structural group ($p<0\ 001$) The same is true

about the phosphorus content (10.51 and 13.87 correspondingly) ($p<0.001$) In the sodium and magnesium contents there are no significant differences between these groups.

In comparison between the mineral contents of otosclerotic bones with abnormal crystalline structure and with amorphous structure, it is noted that the calcium and phosphorus contents in the last mentioned group (18.24 and 10.51) are nearly significantly lower ($p<0.05$) No statistically significant differences are noted in the sodium and magnesium contents between these groups (Table 23)

Table 22. *Comparison between the Ca, P Na and Mg contents of otosclerotic bone with normal crystalline structure (=normal otosclerotic bone) and otosclerotic bone with amorphous structure (=amorphous otosclerotic bone) The mean contents ($\bar{x}$) in mg/100 mg bone.*

may effect somewhat the crystalline structure, so that estimation of results of a material treated in this way must be carried out carefully. On the other hand, treatment of the otosclerotic samples in +60°C water hardly had any effect on the bone crystals, though it is known that bone crystals usually grow in warm water. This is noted as sharpening of diffraction lines.

For the present investigation, the part of the stapedial footplate was chosen which looked most otosclerotic in the operating microscope. Similar morphologic grouping was used by Linck et al. (1967) in their study on the mineral content of the otosclerotic stapedial footplate. They divided the stapedial footplates into four groups, 0 %, 25 %, 50 % and 100 % otosclerotic samples. In addition it must be remembered that the patients from whom the samples had been taken had only clinically manifest otosclerosis. No histologic examination was performed so that it remains at least partly a suggestion that the samples really were otosclerotic. It is true that a part of the samples were examined by microradiography but the microradiographic and Debye-Scherrer samples were not exactly from the same location of the otosclerotic bone.

The mean age of the whole of the present material was 41.7 years, in the group with normal crystalline structure 41.7 years, with abnormal crystalline structure 39.4 years and with amorphous structure 42.4 years. There is no statistically significant differences in the mean ages of the groups. Neither are there statistically significant differences between the sexes. The same is true about the anterior and posterior parts of the stapedial footplate. Thus it seems evident that the different crystalline structures in this material are not dependent of the age, sex or original location of the sample, but the different structures are connected with the otosclerotic process itself.

In the present investigation no attemps were made to elucidate the finer structure of the deviating crystals. It was not possible to do it by the methods used. On the other hand, it must be kept in mind that investigators do not fully agree as to the crystalline structure of hydroxyapatite. The fact that no abnormal structures were found in Group C well agrees with the generally accepted view that in the upper parts of the stapedial crura or in the head of the stapes otosclerotic changes do not occur.

It is not correct to think that otosclerotic bone could generally be divided into different groups with normal and abnormal crystalline structures and amorphous structure, expressed in percentages. The results of this investigation mean of course that a certain amount of the bone needles examined belonged to each structural type. It is probable that if a sufficient number of bone needles would have been prepared of one and the same otosclerotic stapes Debye-Scherrer patterns showing both normal, abnormal and amorphous structures would have been obtained. Namely the fact is that all stages of the otosclerotic process can be found in one otosclerotic focus.

According to Oesterle (1933) cartilage may remain even in remarkable amounts in the bases of the stapedial crura for the whole life. This must also be kept in mind when the amount of samples with amorphous structure is analysed. It could be thought that the amorphous structure here would not represent otosclerotic bone but normal cartilage with no crystalline structure. In Altmann's (1962) opinion after the otosclerotic process has destroyed the cartilaginous covering of the window frame calcification occurs in the proliferated fibrous tissue, and thus is an ankylosing bridge formed at least in some cases in the stapedial footplate. This bridge is then resorbed while the actual otosclerotic bone grows in its place. On the other hand, it seems probable that the diffraction pattern of the calcified ankylosing bridge corresponds to that of hydroxyapatite. Diffraction patterns of calcifications

VI Discussion

A. X ray crystallographic examination

There are very few publications on crystallographic examinations of the normal auditory ossicles Meurman et al (1967 1968) published results of a study which was a preliminary report of the present investigation The present author examined the auditory ossicles of ten patients with no history of impaired hearing and found no diffraction patterns different from that of normal hydroxyapatite Similarly no abnormal crystallographic characteristics were noted in the bone pieces from the posterior meatal wall either in otosclerotic or healthy subjects. It is considered rather certain that the bone tissue of normal auditory ossicles as well as of normal and otosclerotic temporal bone does not differ from normal human bone as to the crystalline structure It must be remembered, however that histologic otosclerosis occurs in about 10 % of the population though only about 1 % has any clinical symptoms (Guild 1944 Larsson 1960 Altmann 1962) Thus it is presumable that histologic otosclerosis may occur in the so-called normal auditory ossicles The fact that there were no abnormal crystalline structures in the normal auditory ossicles may be due either to the real absence of otosclerotic changes in normal stapedes or absence of abnormal crystalline structures despite otosclerotic changes Nevertheless it can be thought that if there are otosclerotic changes in the stapedial footplate there are also changes in hearing Primary otosclerosis in the stapedial footplate is rather rare (Altmann 1962) It would have been interesting to examine the bone crystals of otosclerotic malleus and incus by the same method. This kind of material was however not available.

When the crystal orientation of the normal ossicles was examined by the Laue transmission method it was noted that the bone crystals in the handle of the malleus and long crus of the incus were generally arranged parallelly with the long axis The same is true about the anterior crus of the stapes but in the base of it there was great variability in the bone crystal orientation. It must be kept in mind that the crystal orientation examination based on x ray diffraction is only indicative and the complete rings in the Laue photograph do not necessarily mean absence of orientation (Glimcher 1959)

It is apparent however that the bone crystals in the auditory ossicles are oriented in the same way as in other bones i.e., the crystals follow the direction of collagen fibrils Chevance (1961) and Reydon & Smith (1968) observed remarkable variability in collagen fibril arrangement of the stapedial footplate which well agrees with the results of the present investigation

The otosclerotic bone samples of the present series consisted of pieces of stapedes which had been removed at operations for otosclerosis The small size of the samples made it necessary to use thin bone needles instead of powder specimens in the Debye-Scherrer examination Another possibility would have been to mix the powder from the specimens with glue and draw it out to fine fibers The needles were attempted to be made as thin as possible because the compact bone ought to be about 75 μm thick in order to obtain an optimal diffraction photograph (Carlström 1955) In order to eliminate the disturbing background scattering caused by water and the organic component of the bone a part of the samples were extracted by ethylendiamine Deproteinization

may effect somewhat the crystalline structure, so that estimation of results of a material treated in this way must be carried out carefully On the other hand, treatment of the otosclerotic samples in +60 C water hardly had any effect on the bone crystals though it is known that bone crystals usually grow in warm water This is noted as sharpening of diffraction lines.

For the present investigation the part of the stapedial footplate was chosen which looked most otosclerotic in the operating microscope. Similar morphologic grouping was used by Linck et al. (1967) in their study on the mineral content of the otosclerotic stapedial footplate. They divided the stapedial footplates into four groups 0 25 % 50 % and 100 % otosclerotic samples. In addition it must be remembered that the patients from whom the samples had been taken had only clinically manifest otosclerosis. No histologic *examination* was performed so that it remains at least partly a suggestion that the samples really were otosclerotic. It is true that a part of the samples were examined by microradiography but the microradiographic and Debye-Scherrer samples were not exactly from the same location of the otosclerotic bone.

The mean age of the whole of the present material was 41 7 years in the group with normal crystalline structure 41 7 years with abnormal crystalline structure 39 4 years and with amorphous structure 42.4 years. There is no statistically significant differences in the mean ages of the groups. On the *other hand*, it seems probable that the diffraction pattern of the calcified *ankylosing* bridge corresponds to that of hydroxyapatite. Diffraction patterns of calcifications

VI Discussion

A. X-ray crystallographic examination

There are very few publications on crystallographic examinations of the normal auditory ossicles Meurman et al (1967 1968) published results of a study which was a preliminary report of the present investigation The present author examined the auditory ossicles of ten patients with no history of impaired hearing and found no diffraction patterns different from that of normal hydroxyapatite Similarly no abnormal crystallographic characteristics were noted in the bone pieces from the posterior meatal wall either in otosclerotic or healthy subjects It is considered rather certain that the bone tissue of normal auditory ossicles as well as of normal and otosclerotic temporal bone does not differ from normal human bone as to the crystalline structure It must be remembered however that histologic otosclerosis occurs in about 10 % of the population though only about 1 % has any clinical symptoms (Guild 1944 Larsson 1960 Altmann 1962) Thus it is presumable that histologic otosclerosis may occur in the so-called normal auditory ossicles The fact that there were no abnormal crystalline structures in the normal auditory ossicles may be due either to the real absence of otosclerotic changes in normal stapedes or absence of abnormal crystalline structures despite otosclerotic changes. Nevertheless it can be thought that if there are otosclerotic changes in the stapedial footplate there are also changes in hearing Primary otosclerosis in the stapedial footplate is rather rare (Altmann 1962) It would have been interesting to examine the bone crystals of otosclerotic malleus and incus by the same method. This kind of material was however not available.

When the crystal orientation of the normal ossicles was examined by the Laue transmission method it was noted that the bone crystals in the handle of the malleus and long crus of the incus were generally arranged parallelly with the long axis. The same is true about the anterior crus of the stapes but in the base of it there was great variability in the bone crystal orientation. It must be kept in mind that the crystal orientation examination based on x ray diffraction is only indicative and the complete rings in the Laue photograph do not necessarily mean absence of orientation (Glimcher 1959)

It is apparent however that the bone crystals in the auditory ossicles are oriented in the same way as in other bones i.e. the crystals follow the direction of collagen fibrils Chevance (1961) and Reydon & Smith (1968) observed remarkable variability in collagen fibril arrangement of the stapedial footplate which well agrees with the results of the present investigation

The otosclerotic bone samples of the present series consisted of pieces of stapedes which had been removed at operations for otosclerosis The small size of the samples made it necessary to use thin bone needles instead of powder specimens in the Debye-Scherrer examination Another possibility would have been to mix the powder from the specimens with glue and draw it out to fine fibers The needles were attempted to be made as thin as possible because the compact bone ought to be about 75 μm thick in order to obtain an optimal diffraction photograph (Carlström 1955) In order to eliminate the disturbing background scattering caused by water and the organic component of the bone a part of the samples were extracted by ethylendiamine Deproteinization

It is presumed that in the beginning of the otosclerotic process, bone crystals are not observed at all (amorphous structure). Gradually small bone crystals develop the diffraction lines are diffuse and broad. Little by little the crystals grow and reach at the sclerotic stage a size which is not observed in normal bone. It is obvious that in addition to the size, there are other structural changes as well, which are seen as distinct alterations in the diffraction lines.

Attention must be paid to the fact, which was proved by Termine and Posner (1967) that a remarkable part of the mineral content of normal bone may be amorphous calcium phosphate. Termine & Posner suggested furthermore that amorphous calcium phosphate be the first mineral deposited during the calcification process. Fleisch et al. (1964) noted that inorganic pyrophosphate markedly increased the time required for the transformation of amorphous to crystalline calcium phosphate. They proposed that pyrophosphate may be one of the factors that allows a part of the bone mineral to persist in a non-crystalline state. The alkaline phosphatase might be able to accelerate the transformation process. These circumstances must be remembered when the different crystalline structures and their percentages are analysed in this investigation.

Maurer (1967) suggested that the apatite—fibril relationship is changed in otosclerotic bone. In their electron microscope examination Frank et al. (1964) observed small bone crystals in the otospongiotic phase which will agrees with the results of the present investigation. In addition, Frank et al found big crystals even as long as 3 000 Å, but in osteocytic sclerosis only. They did not find crystal of this length in normal bone but certainly in dentinal sclerosis. Furthermore, they suggested that big single crystal develop from octocalcium phosphate. Octocalcium phosphate is known to alter hydroxyapatite e.g., in electron beam. They also proposed that the osteocytic sclerosis is able to alter the vibratory transmission properties of the stapes.

Linck et al. (1967) noted that otosclerotic bone contains as many as three times so much fluoride as meatal bone. On the other hand, it is known that influenced by fuorine apatite crystals are larger more perfect and less soluble (Eanes 1965). It is known though, that if there is a surplus amount of Mg^{++} ions they fill the lattice surface and the crystal growth is ceased. Francis (1969) stated that both polyphosphonates and polyphosphates are efficient inhibitors of hydroxyapatite crystal growth. Furthermore it has been found out that young bone has a wider surface in contact with the surrounding fluid, so that it is more sensitive to the influences of the environment than old bone. It would be interesting to know whether these observations have any connection with the pathologic crystalline structures found in the present investigation.

According to Frost (1962) no distinct orientation of lacunae and canaliculi can be seen in the otosclerotic bone. This agrees with the result of the present Laue examination that at least in a part of otosclerotic foci, bone crystal orientation is missing. On the other hand, the results of the Laue examination can be considered indicative only. Thus, e.g., if the c-axis of bone crystals is parallel to the x-ray beam no "arcing" phenomenon is present though the bone crystals would in fact be oriented. This possibility is rare, though. Lack of preferred orientation is typical not only of otosclerotic bone, because similar arrangement of bone crystals is met in fibrous bone as well, which is present in many bone diseases elsewhere than in the labyrinthine capsule. In crystallizing cartilage as well bone crystals are arranged at random (Robinson & Cameron 1956). The same is true about embryonic bone (Clarc & Iball 1957). All these observations indicate that at its initial stage, otosclerotic bone is young, rapidly developing fibrous bone (Reydon & Smith 1968).

in blood vessel walls correspond to those of hydroxyapatite (Carlström 1955) and so do diffraction patterns of tympanosclerosis (the author's observation)

Three of the diffraction patterns of samples treated with ethylendiamine were abnormal, whereas a normal hydroxyapatite pattern was obtained of the corresponding untreated samples. It is not quite certain, whether the crystalline structures were really pathologic or whether the change was due to deproteinization treatment

When analysing the results, it must be remembered carefully that in the otosclerotic stapes there are at the same time and next to each other areas with quite normal ultrastructure and areas with different otosclerotic changes (Frank et al 1968) Similarly there are otosclerotic foci of different stages side by side in the footplate and these foci develop independently of each other On the other hand the development of the otosclerotic focus may stop and then start again (Hall & Ogilvie 1963) Furthermore otosclerotic changes may be local and diffuse.

Weber observed as early as in 1931 that the collagen fibrils in otosclerotic focus clearly differ from the fibrils outside the focus Chevance (1962) also found different changes in the collagen fibrils of the focus Other investigators (Reydon & Smith 1968) as well have noted changes in the collagen of otosclerotic bone. Soifer et al (1969 b) could not find any abnormal changes in the total amount of collagen in the otosclerotic stapes. Thus the changes are probably qualitative. Frost (1962) thinks that the primary factor in otosclerosis is some change in the cement substance of the labyrinthine capsule What makes osteoblasts produce abnormal cement substance is still unsolved Maurer (1962) thought that generally in the area of fibrous bone the organic component is different from other parts of bone tissue Ardouin & Wegmann (1961) noted disturbances in mucopolysaccharides and polysaccharides in the otosclerotic focus In their investigation Arslan & Ricci (1961) found alterations in the osteomucoid substance Soifer et al (1969b) could not find any changes in the total amount of mucopolysaccharides so that changes seem to be in the different components. Chevance et al (1961 b) and Soifer et al (1969 a) noted that during the active phase of the otosclerotic process, the activity of alkaline phosphatase in the focus has increased. The same phenomenon was observed by Ricci (1962) too As well numerous other enzyme activities have been noted to increase during the active phase of the otosclerotic process (Albernaz & Covell 1961 Ardouin & Wegmann 1961) Soifer et al (1969 a) found however that increase in the alkaline phosphatase and decrease in the lactate dehydrogenase activities alone are statistically significant All these observations indicate abnormal changes in the organic component of the otosclerotic focus. In normal bone, the crystals are arranged in line with collagen fibrils and it is proposed that there are apparently three crystallites for each 640 Å period of the collagen fibril Some kind of a connection has been noted between the crystal size and repeating units of the collagen fibrils. In the light of these investigations, a very interesting observation was made by Reydon & Smith (1968) They found that in the otosclerotic stapes the dense band in the collagen period appeared wider than that in bone collagen from normal stapes

On the basis of the present investigation it is obvious that besides the normal hydroxyapatite crystalline structure there are also abnormal crystalline structures in the otosclerotic focus. In addition fibrous tissue is apparently present in which distinct crystal formation has not taken place yet That is why this tissue gives a diffraction pattern typical of the amorphous structure In a part of the photographs, the lines are broad and ill-defined which indicates that most of the crystals are small in their siz

It is presumed that in the beginning of the otosclerotic process bone crystals are not observed at all (amorphous structure) Gradually small bone crystals develop the dif fraction lines are diffuse and broad. Little by little the crystals grow and reach at the sclerotic stage a size which is not observed in normal bone. It is obvious that in addition to the size there are other structural changes as well, which are seen as distinct alterations in the diffraction lines.

Attention must be paid to the fact, which was proved by Termine and Posner (1967) that a remarkable part of the mineral content of normal bone may be amorphous calcium phosphate. Termine & Posner suggested furthermore that amorphous calcium phosphate be the first mineral deposited during the calcification process. Fleisch et al (1968) noted that inorganic pyrophosphate markedly increased the time required for the transformation of amorphous to crystalline calcium phosphate. They proposed that pyrophosphate may be one of the factors that allows a part of the bone mineral to persist in a non-crystalline state. The alkaline phosphatase might be able to accele rate the transformation process. These cir cumstances must be remembered when the different crystalline structures and their per centages are analysed in this investigation.

B. Microradiographic examination

Karlsson et al (1954) and Orlandini & Sbernini (1956) have studied normal auditory ossicles employing microradiographic methods In the present investigation this was not done the primary aim being to determine the mineral content of otosclerotic bone by quantitative microradiography Nevertheless otosclerotic bone in its active phase differs so much from normal bone that the traditional microradiographic methods were difficult to apply First of all the strong porosity of active otosclerotic bone caused difficulties This was also noted by Garcia Ibañez (1968) In the present investigation an additional source of error was the fact that the methylmethacrylate sections were not plane parallel Furthermore determination of the section thicknesses was inaccurate Because of these reasons the conclusions drawn by quantitative microradiography were only indicative.

The developmental stage of the otosclerotic bone was tried to be determined by microradiographs The present author wanted to obtain suggestions at what developmental stage of otosclerosis varying crystalline structures observed in the Debye-Scherrer analysis occur and whether they are in any way connected with the otosclerotic process In estimation of the developmental stage traditional histologic methods would obviously have been more useful (Henner et al 1960) Because of the great number of methods and scarcity of material it was necessary to limit the investigation to the microradiographic examination The same methylmethacrylate sections had previously been used in the Laue examination

Fifty otosclerotic bone samples were studied by microradiographic methods 30 of them had normal and 10 abnormal crystalline structure and 10 had amorphous structure. All samples were either from the anterior part of the stapedial footplate or macroscopically distinct separate otosclerotic foci Thus the material was selected up to a great extent and it cannot be compared with unselected otosclerotic stapes material The material was grouped according to which type of the process was the most dominating

In the pertinent literature there are several principles according to which the otosclerotic process is divided. Nylén (1949) called the different types local and diffuse otosclerosis In his material 10 % was diffuse. The foci were active (20 %) quiescent (30 %) and mixed (50 %) Ogilvie & Hall (1953 1962) used the division into local and diffuse as well and the developmental stages were called by them active quiescent healing and healed Ludman (1962) again divided his otosclerotic material as follows 1 early focal (10 %) 2 active diffuse (38 %) 3 quiescent (52 %) Ludman suggested two different types of clinical otosclerosis. Wolff & Bellucci (1964) divided the otosclerotic changes into six types They also emphasized that division of the samples is very difficult because under the microscope it is possible to see several types and stages of the disease in the view of field at one and the same time. Gukovich (1964) used the following division 1 immature foci (high activity) 2 foci with medium degree of maturity (moderate activity) 3 mature foci (low activity) When attention is also paid to the fact that no distinct lines can be drawn between the different types and stages presenting of percentages is greatly based on the investigator s subjective opinion

As has been mentioned earlier the aim of the microradiographic examination was to elucidate the occurrence of the three crystalline structures at various developmental stages of otosclerosis Certain conclusions were not possible to draw because the bone sample for the Debye-Scherrer analysis was not from exactly the same place in the original preparation as the sample for the microradiographic examination. It is possible that both sample groups included oto-

sclerotic bone material of quite a different stage and type. That is why the distribution in percentages must be analysed with reservation. Nevertheless it is very probable that the samples which were classified amorphous on the basis of the Debye-Scherrer analysis represent the youngest and most active otosclerotic process, in which bone crystals have not developed yet or are still very small and imperfect. On the other hand, with regard to the samples with abnormal crystalline structure, the conclusion is not so clear because they can obviously appear both in younger and in older inactive otosclerotic bone.

C. Quantitative mineral analysis

In the present investigation, the phosphorus and sodium contents were determined by neutron activation analysis and the calcium and magnesium contents by atom absorption spectrophotometry. The methods can be considered relatively accurate at least for calcium and phosphorus because the determination accuracy of these elements was estimated about ± 3 %. For sodium the accuracy was ± 5 % and for magnesium it was only ± 10—20 %. The small size of the samples caused difficulties, but excluding some individual cases the results can be considered reliable.

Samples of the anterior part of the stapedial footplate were chosen as control material because the otosclerotic material also represented the anterior part of the footplate or separate otosclerotic foci. It must be kept in mind, as has been earlier mentioned, that in the bases of the stapedial crura, there may be an abundance of cartilage (Oesterle 1933). This may cause false results in the analyses both of control and otosclerotic samples. The mineral analysis results of calcium in control material rather well agree with the average calcium content of 30.0 % obtained by Maurer (1960). Maurer (1967) continued his investigations, and measured the corresponding figure 29.4 %. The value for phosphorus in the present investigation 15.96 % is higher than the percentages by Maurer (13.7 % in 1960 and 13.7 % in 1967). This variation may be due to differences in the measuring techniques.

The following values were obtained in normal stapes by Soifer et al. (1970 a): calcium 29.2 % and phosphorus 11.1 % and by Soifer et al. (1970 b): calcium 28.6 %, sodium 0.766 % and magnesium 0.325 %. It must be remembered, however, that both Maurer and Soifer et al. used whole stapedes in their measurements.

The otosclerotic material in the mineral analysis was selected, so that it is difficult to compare these results with the earlier ones. In the first place, comparisons could be carried out with otosclerotic material with normal crystalline structure but not even this group is completely comparable with unselected otosclerotic material. Furthermore all measurement results have been obtained either from the anterior part of the otosclerotic stapedial footplate or a separate otosclerotic focus. In other words from the most otosclerotic locations, whereas Maurer (1967) and Soifer et al. (1970 a, 1970 b) used whole stapedes also in their analyses of otosclerotic material. Maurer (1967) emphasized that the stapedes in his material did not include at least macroscopically observable otosclerotic foci, whereas it was expressly aimed at in the present investigation. Nevertheless, when the bone samples are smaller also measuring errors grow. In addition, in one and the same bone, mineral contents may vary a great deal even in a very small area. A more descriptive method would obviously be to determine the mineral contents per unit volume because the structure of otosclerotic bone would then be better revealed (Röckert et al. 1965). Maurer (1967) found the average calcium content of otosclerotic stapes to be 29.2 % and the average phosphorus content 13.4 %. Soifer et al. (1970 a)

obtained the corresponding values 28.4 % and 11.0 % and Soifer et al (1970 b) for calcium 27.5 % magnesium 0.327 % and sodium 0.869 %. Soifer et al (1970 a) could not find a correlation on one hand between the calcium and phosphorus contents and on the other hand between the sex age or otosclerotic growth in footplates.

It is interesting to compare the mineral contents between the different otosclerotic groups of the present investigation and normal stapedial footplate. Maurer (1967) observed that the calcium and phosphorus contents of the otosclerotic stapes were significantly lower than the corresponding values of the normal stapes. On the other hand Soifer et al (1970 a) did not note a statistically significant difference between corresponding groups. Linck et al (1967) found out that even a 100 % otosclerotic stapedial footplate contained less calcium than a normal one. It was observed in the present investigation that the calcium and phosphorus contents of otosclerotic bone with normal crystalline structure were significantly lower than those of normal stapedial bone. No difference was noted between the sodium contents and the magnesium content was nearly significantly lower.

Between otosclerotic samples with normal and abnormal crystalline structures no statistically significant differences were noted for any of the minerals examined. Neither were there any clear differences between these groups in the microradiographic examination. It is quite obvious that these two groups need not be separated and they do not necessarily represent different phases in the otosclerotic process. On the basis of the present results it seems also apparent that crystalline structures deviating from the normal hydroxyapatite may occur as well in young rather active as in older inactive otosclerotic foci.

Amorphous otosclerotic bone however clearly differs from normal otosclerotic bone with regard to its minerals. Both calcium and phosphorus contents in otosclerotic bone were in this group highly significantly lower than those of the normal stapes or otosclerotic bone with normal crystalline structure. On the other hand the sodium and magnesium contents did not differ from the corresponding values of normal otosclerotic bone. This mineral analysis supports the earlier suggestion that amorphous otosclerotic bone represents a young, active focus whose mineral content is low and bone crystals have not yet developed properly.

In order to find out whether otosclerosis is a local or more generalized process changes in the mineral contents of serum have been examined but the results have been partly conflicting. As well alkaline phosphatase activity in sera from otosclerotics have been determined and possible correlations looked for in it but even these results have turned out somewhat conflicting. Determination of different hormones and their catabolites has been attempted to be elucidated knowing the connection between hormones and bone metabolism but no certain conception of the hormonal status of otosclerotic patients has been obtained. Vysloužil's (1961 1963) observations on high estrogen levels in otosclerotics seem somewhat more reliable.

Maurer (1967) drew the conclusion that in otosclerosis the fibrillar content is higher than normally in areas consisting mainly of web-like bone. He deduced from this that the otosclerotic process is not only local. True Pedersen & Sörensen (1970) examined normal and otosclerotic stapedial crura in light and electron microscopy but could find no differences in the periosteum or bone tissue. This again speaks against a general ized connective tissue disease. On the other hand observations on lower mineral contents than normally in the malleus and incus in connection with otosclerosis indicate a more generalized process (Mello & Sillingardi 1952 Flor & Martinozzi 1960 Evens &

Henkin 1969) It must be remembered however that alterations in the mineral contents of all auditory ossicles may be secondary changes resulting from stapedial ankylosis in other words, osteoporosis caused by impaired motility No certain conclusion can however be drawn whether otosclerosis is merely a local disease of the labyrinthine capsule or a local manifestation of a more generalized disorder

obtained the corresponding values 28.4 % and 11.0 % and Solfer et al (1970 b) for calcium 27.5 % magnesium 0.327 % and sodium 0.869 % Solfer et al (1970 a) could not find a correlation on one hand between the calcium and phosphorus contents and on the other hand between the sex age or otosclerotic growth in footplates.

It is interesting to compare the mineral contents between the different otosclerotic groups of the present investigation and normal stapedial footplate Maurer (1967) observed that the calcium and phosphorus contents of the otosclerotic stapes were significantly lower than the corresponding values of the normal stapes. On the other hand Solfer et al (1970 a) did not note a statistically significant difference between corresponding groups Linck et al (1967) found out that even a 100 % otosclerotic stapedial footplate contained less calcium than a normal one. It was observed in the present investigation that the calcium and phosphorus contents of otosclerotic bone with normal crystalline structure were significantly lower than those of normal stapedial bone No difference was noted between the sodium contents and the magnesium content was nearly significantly lower

Between otosclerotic samples with normal and abnormal crystalline structures no statistically significant differences were noted for any of the minerals examined. Neither were there any clear differences between these groups in the microradiographic examination It is quite obvious that these two groups need not be separated and they do not necessarily represent different phases in the otosclerotic process On the basis of the present results it seems also apparent that crystalline structures deviating from the normal hydroxyapatite may occur as well in young rather active as in older inactive otosclerotic foci

Amorphous otosclerotic bone however clearly differs from normal otosclerotic bone with regard to its minerals Both calcium and phosphorus contents in otosclerotic bone were in this group highly significantly lower than those of the normal stapes or otosclerotic bone with normal crystalline structure. On the other hand the sodium and magnesium contents did not differ from the corresponding values of normal otosclerotic bone. This mineral analysis supports the earlier suggestion that amorphous otosclerotic bone represents a young active focus whose mineral content is low and bone crystals have not yet developed properly

Henkin 1969). It must be remembered, however that alterations in the mineral contents of all auditory ossicles may be secondary changes resulting from stapedial ankylosis, in other words osteoporosis caused by impaired motility. No certain conclusion can, however be drawn whether otosclerosis is merely a local disease of the labyrinthine capsule or a local manifestation of a more generalized disorder

VII Summary

The aim of the study was to investigate by the Debye Scherrer method the crystalline structures of normal auditory ossicles and otosclerotic bone by comparing them with the crystalline structure of normal human bone. In addition crystal orientation in normal auditory ossicles and otosclerotic bone was investigated by the Laue transmission method. By virtue of the microradiographic examination the present author attempted to find out at what developmental stage of otosclerosis alterations in the crystalline structure appear. Finally the mineral contents of the normal stapes and different otosclerotic foci observed by the x-ray crystallographic examination were studied. The calcium and magnesium contents were determined by atom absorption spectrophotometry and the phosphorus and sodium contents by neutron activation analysis.

The auditory ossicles of 10 deceased with no history of impaired hearing were examined by the Debye-Scherrer method. Powder patterns were made of seven different locations of the ossicular chain. All diffraction patterns were identical with that of normal human bone. As well the diffraction patterns of the posterior meatal wall of controls and otosclerotics were identical with the pattern of normal hydroxyapatite.

The auditory ossicles of 10 deceased with no history of impaired hearing were examined by the Laue transmission method. It was noted that the bone crystals were arranged parallelly with the collagen fibrils. In the stapedial footplate however great variation was noted in the bone crystal orientation.

The otosclerotic material consisted of 250 samples obtained in connection with operations for otosclerosis. They were pieces of otosclerotic stapedes or separate otosclerotic foci. In the Debye-Scherrer examination, a diffraction pattern of normal hydroxyapatite was obtained in 75 %, an abnormal pattern in 7 % and a pattern typical of amorphous structure in 18 %. As to the stapedial foot plate alone in 73 % of the 237 samples examined the diffraction pattern was that of normal hydroxyapatite, 8 % gave an abnormal pattern and 19 % a pattern showing amorphous structure. The patterns of the different crystalline structures did not correlate in any way with the sex or age of the patients or original location of the sample.

Bone crystal orientation was examined in 50 otosclerotic samples. In 24 % a more or less preferred orientation was noted whereas no preferred orientation was seen in 68 %. In the samples with the normal crystalline structure preferred orientation was observed in 25 %, whereas in the samples with the abnormal crystalline structure preferred orientation was seen in 20 % and no preferred orientation in 80 %.
